Micronutrient Information Center

The Linus Pauling Institute's Micronutrient Information Center is a source for scientifically accurate information regarding the roles of vitamins, minerals, phytochemicals (plant chemicals that may affect health), and other dietary factors, including some food and beverages, in preventing disease and promoting health. All of the nutrients and dietary factors included in the Micronutrient Information Center may be obtained from the diet, and many are also available as dietary supplements.

MIC Home

About

Español

The Linus Pauling Institute's Micronutrient Information Center (MIC) is a source for scientifically accurate information on the functions and health effects of all micronutrients (vitamins and nutritionally essential minerals); other nutrients like choline and essential fatty acids; dietary factors, including many phytochemicals (non-nutritive plant chemicals that may affect health); and some food and beverages, including tea, coffee, and alcohol. All of the nutrients and dietary factors included in the MIC may be obtained from the diet, and many are also available as dietary supplements; dietary and supplemental sources are discussed in each article.

Human research is emphasized in the MIC, although cell culture or animal studies may be mentioned when human studies are lacking. Most MIC articles have summaries at the beginning and include the following subsections: Function or Biological Activities, Metabolism and Bioavailability, Deficiency, The RDA or AI (for males and females of various age groups), Disease Prevention, Disease Treatment, Sources (food and supplements), and Safety (toxicity and drug or nutrient interactions). For the micronutrients (vitamins and essential minerals), the Linus Pauling Institute provides a daily intake recommendation.

For each article, Ph.D. nutrition scientists critically review and synthesize basic, clinical, and epidemiological studies in the peer-reviewed literature and provide references throughout. Each article is then additionally reviewed by an expert in the field; the names of the authors and reviewers are listed at the bottom of each article. This multiple review process minimizes bias and presents objective information.

In order to keep this website freely available (and free from ads), we rely on outside funding. This comes in part from corporate sponsorships. We provide information about corporate funders, if applicable, at the bottom of each article. We thank DSM Nutritional Products, LLC for providing general funding to develop content on health and disease topics. Financial sponsors do not have editorial control over the content on this website.

In addition to business sponsors, the Micronutrient Information Center is supported by your donations. If you value this website, please help by donating to LPI Outreach Education Fund.

We welcome your inquiries and feedback via email.

Journalists wishing to contact members of the Linus Pauling Institute can consult our media contact page. The Micronutrient Information Center staff can be contacted directly though email.

Vitamins

Español

The term vitamin is derived from the words vital and amine, because vitamins are required for life and were originally thought to be amines. Although not all vitamins are amines, they are organic compounds required by humans in small amounts from the diet. An organic compound is considered a vitamin if a lack of that compound in the diet results in overt symptoms of deficiency.

The information from the Linus Pauling Institute's Micronutrient Information Center on vitamins and minerals is now available in a book titled, *An Evidence-based Approach to Vitamins and Minerals: Health Benefits and Intake Recommendations*. The book can be purchased from the Linus Pauling Institute or Thieme Medical Publishers.

Summary

- Water-soluble biotin is an essential cofactor to enzymes in intermediary metabolism and a key regulator of gene expression. *(More information)*
- Both parenteral nutrition devoid of biotin and prolonged consumption of raw egg white have been associated with symptoms of frank biotin deficiency, including hair loss, dermatitis, skin rash, ataxia, seizures, and other neurologic dysfunctions. *(More information)*
- Biotinidase deficiency is a rare hereditary disorder that impairs biotin absorption and recycling, resulting in secondary biotin deficiency. *(More information)*
- The recommended adequate intake (AI) of biotin is set at 30 micrograms (μg)/day in adults. Biotin requirements are likely increased during pregnancy and breast-feeding. *(More information)*
- Animal studies have shown that biotin sufficiency is essential for normal fetal development. Yet, it is not known if marginal biotin deficiency during pregnancy increases the risk for congenital anomalies in humans. *(More information)*
- Biotin is used in the treatment of biotin-thiamin responsive basal ganglia disease, an inherited disorder of thiamin transport. *(More information)*
- Recent randomized controlled trials have not found high-dose biotin supplementation to be beneficial in the treatment of multiple sclerosis. Yet, results of animal studies and meta-analyses of human clinical trials are promising. *(More information)*
- Definitive evidence that establishes whether biotin supplementation improves glucose and lipid homeostasis in individuals with type 2 diabetes mellitus is currently lacking, but suggestive observations have been published. *(More information)*
- Biotin cannot be synthesized by mammalian cells and must be obtained from exogenous sources. Biotin is widely found in food, and good dietary sources include egg yolk, liver, whole-grain cereal, and some vegetables. *(More information)*
- Long-term anticonvulsant (anti-seizure) therapy may increase the dietary requirement for biotin because anticonvulsants can interfere with the intestinal absorption and renal re-absorption of biotin and likely also increase degradation of biotin to inactive metabolites. *(More information)*
- Use of high-dose biotin supplements can result in aberrant results of laboratory tests that utilize the very high affinity biotin-streptavidin (avidin) interaction. *(More information)*

Biotin is a water-soluble vitamin that is generally classified as a B-complex vitamin. After its initial discovery in 1927, 40 years of additional research was required to unequivocally establish biotin as a vitamin (1). Biotin is required by all organisms but can be synthesized by some strains of bacteria, yeast, mold, algae, and some plant species (2).

Function

Biotinylation

Biotin functions as a covalently bound cofactor required for the biological activity of the five known mammalian biotin-dependent carboxylases (see below). Such non-protein cofactors are termed "prosthetic groups" and are common in water-soluble vitamins. The covalent attachment of biotin to the apocarboxylase (i.e., the carboxylase protein without the biotin prosthetic group and is catalytically inactive) is catalyzed by the enzyme, holocarboxylase synthetase (HCS). The term "biotinylation" refers to the covalent addition of biotin to any molecule, including the apocarboxylases and histones. HCS catalyzes the post-translational biotinylation of the epsilon amino group of a lysine residue at the active site of each apocarboxylase, converting the inactive apocarboxylase into a fully active holocarboxylase (**Figure 1a**). Particular lysine residues within the N-terminal tail of specific histone that help package DNA in eukaryotic nuclei can also be biotinylated (3). Biotinidase is the enzyme that catalyzes the release of biotin from biotinylated histones and from the peptide products of holocarboxylase breakdown (**Figure 1b**).

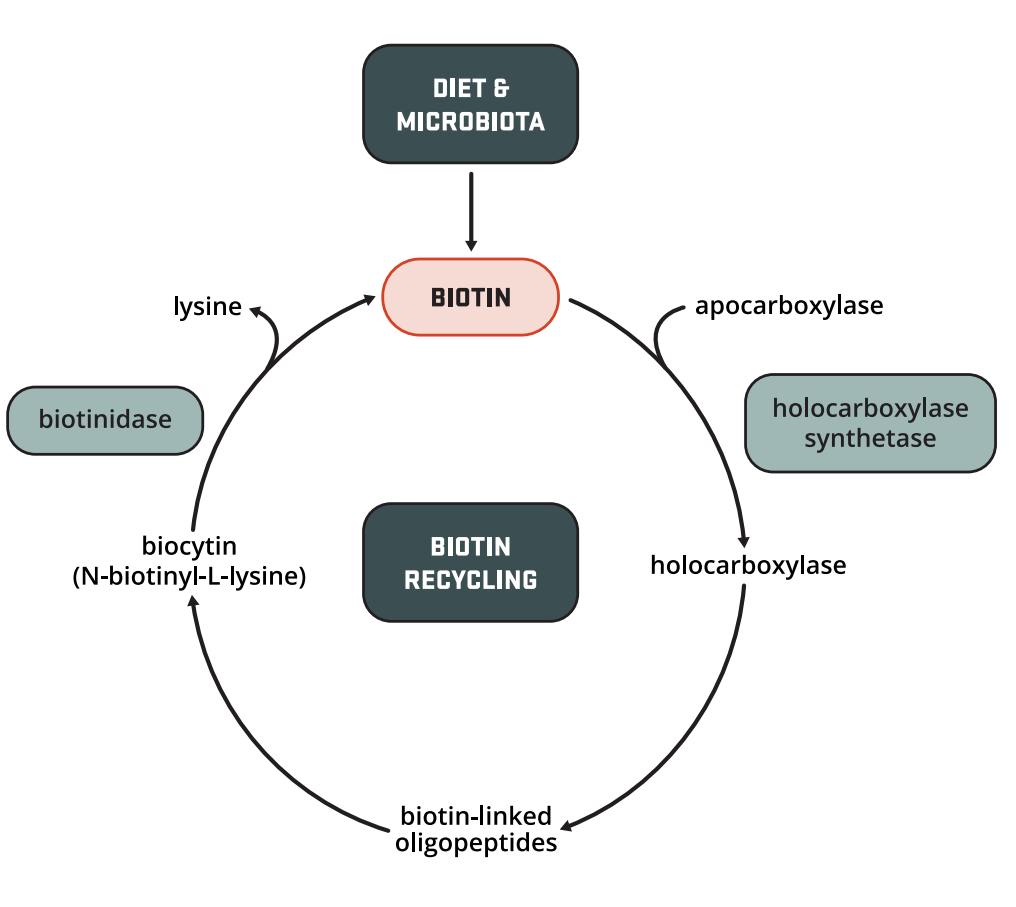
REQUIRE BIOTIN FOR BIOLOGICAL ACTIVITY:
acetyl-CoA carboxylases 1 & 2
pyruvate-CoA carboxylase
propionyl-CoA carboxylase
methylcrotonyl-CoA carboxylase
ATP - adenosine triphosphate
CoA - coenzyme A
PPi - pyrophosphate

Holocarboxylase synthetase catalyzes the transfer of biotin to a specific lysine residue at the active site of apocarboxylase, converting the enzyme to a fully active holocarboxylase. Five mammalian carboxylases are known to require biotin for their biological activity: acetyl-CoA carboxylases 1 and 2, pyruvate-CoA carboxylase, propionyl-CoA carboxylase, and methylcrotonyl-CoA carboxylase.

Figure 1b. Biotin Recycling



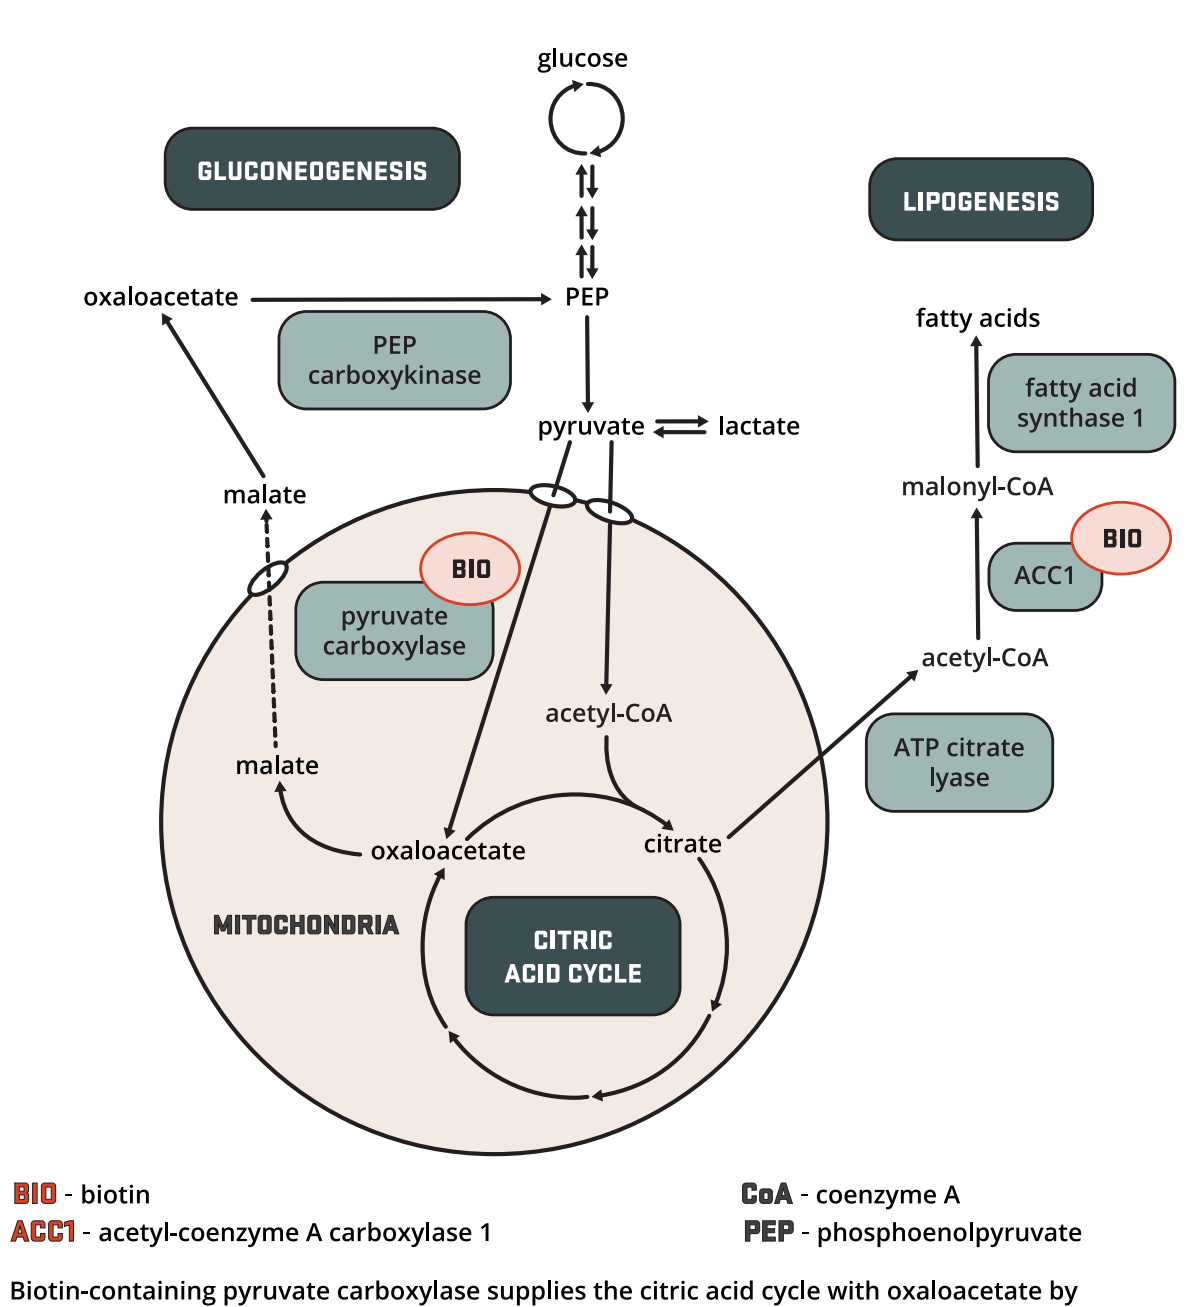
The biotinylation of apocarboxylase is catalyzed by holocarboxylase synthetase, while the enzyme biotinidase catalyzes the removal of biotin from the peptide products of carboxylase breakdown.

Enzyme cofactor

Five mammalian carboxylases catalyze essential metabolic reactions:

• Both **acetyl-Coenzyme A (CoA) carboxylase 1 (ACC1)** and **acetyl-CoA carboxylase 2 (ACC2)** catalyze the conversion of acetyl-CoA to malonyl-CoA using bicarbonate and ATP; however, the two enzymes have different roles in metabolism and different intracellular locations. ACC1 is located in the cytosol, and the malonyl CoA generated by ACC1 is a rate-limiting substrate for the synthesis of fatty acids (**Figure 2**). ACC1 is found in all tissues and is particularly active in lipogenic tissues (i.e., liver, white adipose tissue, and mammary gland), heart, and pancreatic islets. ACC2 is located on the outer mitochondrial membrane, and the malonyl CoA generated via ACC2 inhibits CPT1, an enzyme that regulates malonyl-CoA entry into the inner mitochondria, thereby regulating fatty acid oxidation (**Figure 3**). ACC2 is especially abundant in skeletal muscle and heart (4).

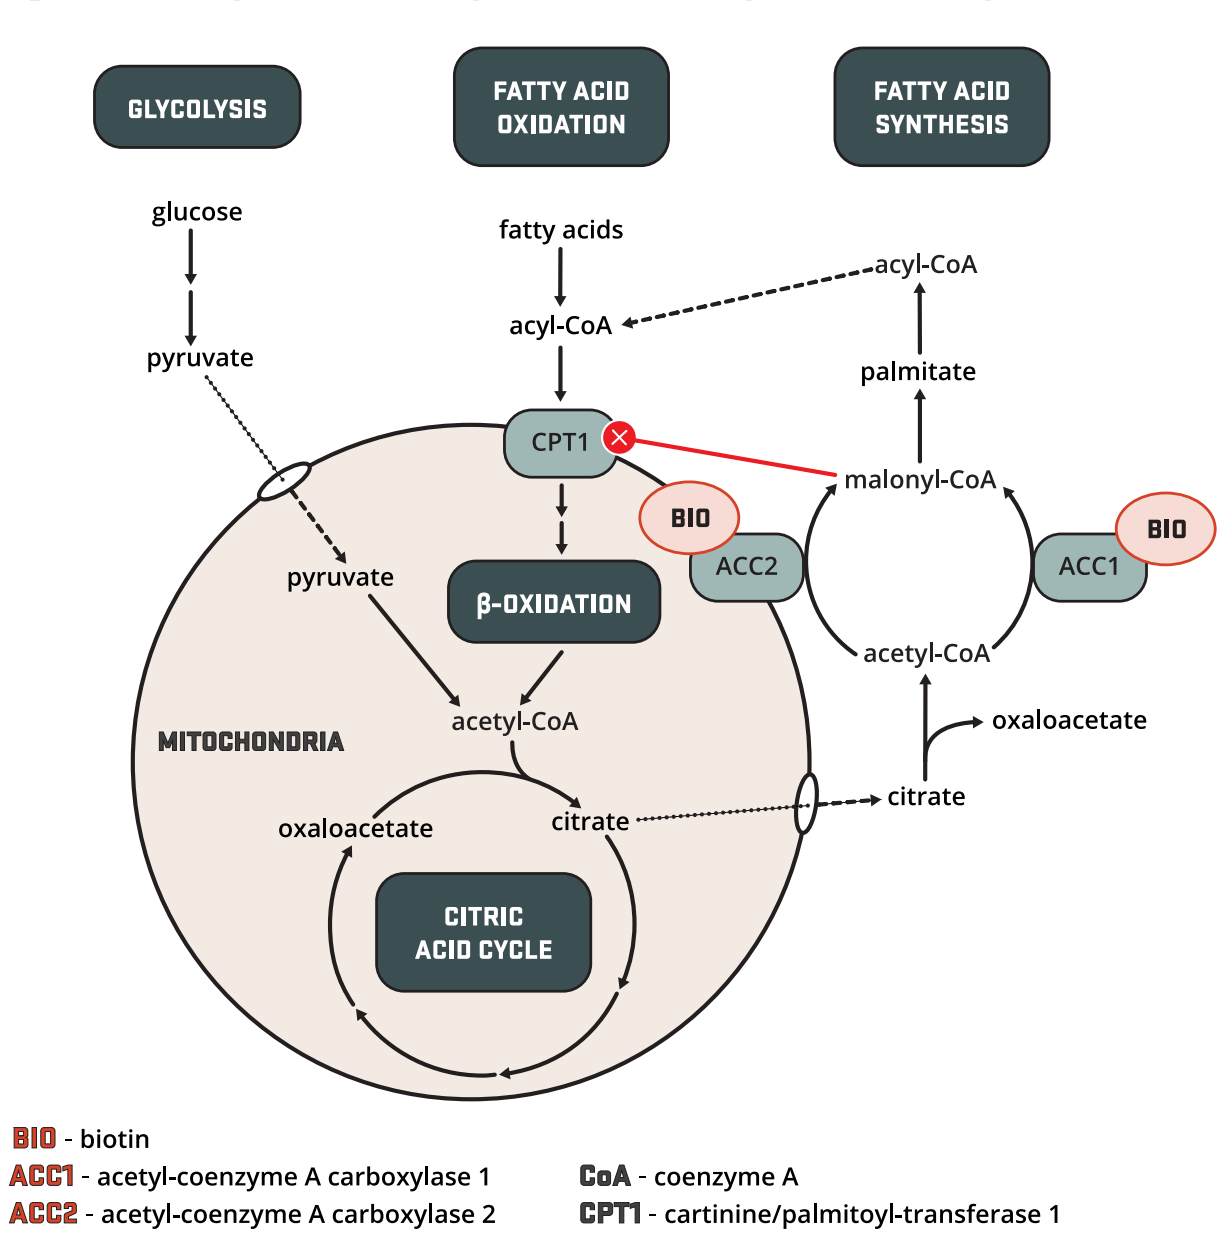
Figure 2. Pyruvate Carboxylase and Acetyl-CoA Carboxylase 1



Biotin-containing pyruvate carboxylase supplies the citric acid cycle with oxaloacetate by catalyzing the conversion of pyruvate to oxaloacetate using bicarbonate and ATP. In the liver, oxaloacetate can be used as a precursor for gluconeogenesis. It is first converted to phosphoenolpyruvate (PEP) by PEP carboxykinase and then to glucose via the reverse pathway of glycolysis. In the citric acid cycle, oxaloacetate can also be condensed with acetyl-CoA to produce citrate, which can be exported from the mitochondria. In the liver, adipose tissue, and skeletal muscle, citrate is cleaved to oxaloacetate and acetyl-CoA in the cytosol. Acetyl-CoA is converted to malonyl-CoA by another biotin-containing enzyme, acetyl-CoA carboxylase 1. Malonyl-CoA is then used by fatty acid synthase 1 to generate long-chain fatty acids.

• **Pyruvate carboxylase** is a critical enzyme in gluconeogenesis (the formation of glucose from sources other than carbohydrates, such as pyruvate, lactate, glycerol, and the glucogenic amino acids). Pyruvate carboxylase catalyzes the ATP-dependent incorporation of bicarbonate into pyruvate, producing oxaloacetate; hence, pyruvate carboxylase is anaplerotic for the citric acid cycle (**Figure 3**). Oxaloacetate can then be converted to phosphoenolpyruvate and eventually to glucose.

Figure 3. Acetyl-CoA Carboxylase 1 and Acetyl-CoA Carboxylase 2

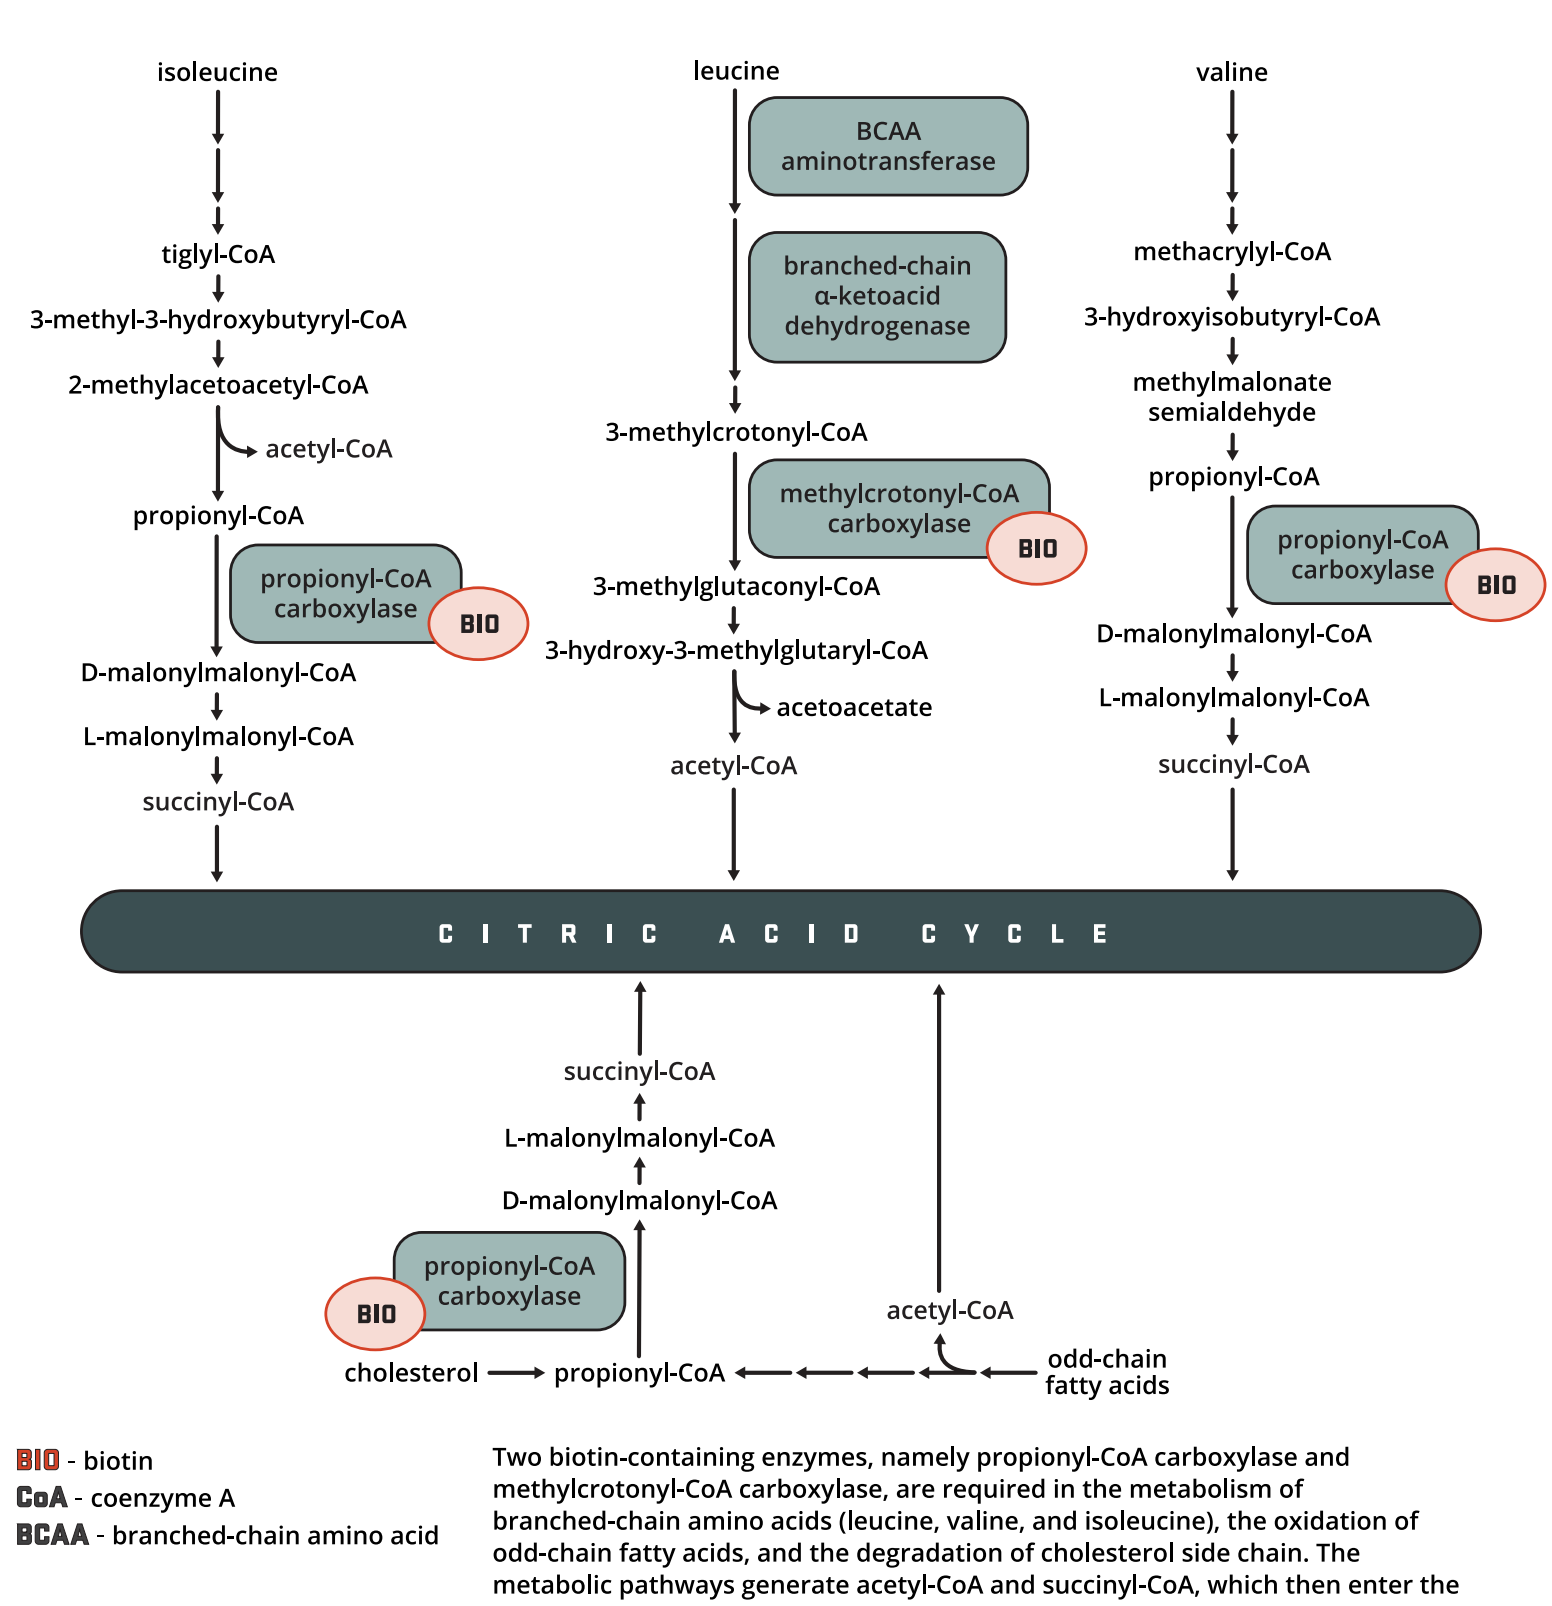


In the cytosol of liver cells, fatty acids are converted to acyl-CoA, and glucose undergoes glycolysis that produces pyruvate. Acyl-CoA is shuttled into the mitochondria via CPT1-mediated transport and undergoes β-oxidation that generates acetyl-CoA. In addition, pyruvate is converted to acetyl-CoA in the mitochondria, and acetyl-CoA is condensed with oxaloacetate to form citrate. The latter can be exported to the cytosol and cleaved to oxaloacetate and acetyl-CoA. Acetyl-CoA is used to generate malonyl-CoA in a reaction catalyzed by biotin-containing acetyl-CoA carboxylase 1 (ACC1) in the presence of ATP and bicarbonate. Malonyl-CoA is an essential substrate for the biosynthesis of fatty acids and subsequent triglycerides, phospholipids, and lipoproteins. Malonyl-CoA is also a regulator of fatty acid β-oxidation. Indeed, malonyl-CoA generated from acetyl-CoA by another biotin-containing enzyme, acetyl-CoA carboxylase 2 (ACC2), localized at the mitochondrial membrane, has been shown to downregulate fatty acid β-oxidation in the mitochondria by inhibiting CPT1.

• **Methylcrotonyl-CoA carboxylase** catalyzes an essential step in the catabolism of leucine, an essential branched-chain amino acid. This enzyme catalyzes the production of 3-methylglutaconyl-CoA from methylcrotonyl-CoA (**Figure 4a**).

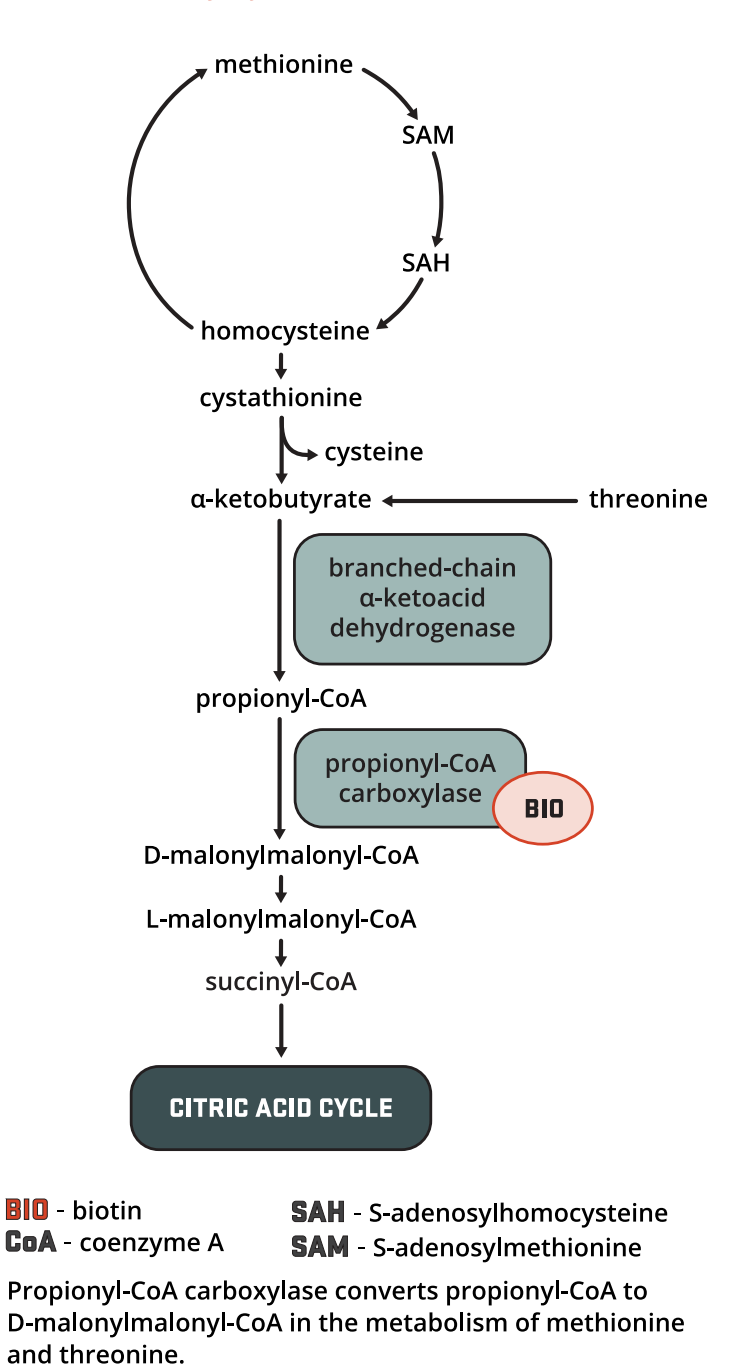
• **Propionyl-CoA carboxylase** produces D-malonylmalonyl-CoA from propionyl-CoA, a by-product in the β-oxidation of fatty acids with an odd number of carbon atoms (**Figure 4a**). The conversion of propionyl-CoA to D-malonylmalonyl-CoA is also required in the catabolic pathways of two branched-chain amino acids (isoleucine and valine) and the side chain of cholesterol (**Figure 4a**) and of the amino acids methionine and threonine (**Figure 4b**).

Figure 4a. Biotin-containing Carboxylases in the Metabolism of BCAAs, Odd-Chain Fatty Acids, and Cholesterol



Two biotin-containing enzymes, namely propionyl-CoA carboxylase and methylcrotonyl-CoA carboxylase, are required in the metabolism of branched-chain amino acids (leucine, valine, and isoleucine), the oxidation of odd-chain fatty acids, and the degradation of cholesterol side chain. The metabolic pathways generate acetyl-CoA and succinyl-CoA, which then enter the citric acid cycle.

Figure 4b. Biotin-containing Propionyl-CoA Carboxylase in the Metabolism of Methionine and Threonine



Propionyl-CoA carboxylase converts propionyl-CoA to D-malonylmalonyl-CoA in the metabolism of methionine and threonine.

Regulation of chromatin structure and gene expression

In eukaryotic nuclei, DNA is packaged into compact structures to form nucleosomes — fundamental units of chromatin. Each nucleosome is composed of 147 base pairs of DNA wrapped around eight histones (paired histones: H2A, H2B, H3, and H4). The H1 linker histone is located at the outer surface of each nucleosome and serves as an anchor to fix the DNA around the histone core. The compact packaging of chromatin must be relaxed for DNA replication and transcription. Chemical modifications of DNA and histones affect the folding of chromatin, increasing or reducing DNA accessibility to factors involved in replication and transcription. DNA methylation and a number of chemical modifications within the N-terminal tail of core histones modify their electric charge and structure, thereby changing chromatin conformation and transcriptional activity of genes.

The modifications of histone tails ("marks"), including acetylation, methylation, phosphorylation, ubiquitination, SUMOylation, ADP-ribosylation, carbonylation, deimination, hydroxylation, and biotinylation, have various regulatory functions. Several sites of biotinylation have been identified in histones H2A, H3, and H4 (5). Amongst them, histone H4 biotinylation at lysine (K) 12 (noted H4K12bio) appears to be enriched in heterochromatin, a tightly condensed chromatin associated with repeat regions in (peri)centromeres and telomeres. H4 biotinylation appears to be enriched in transposable elements known as long terminal repeats (3). These biotinylation marks also co-localize with well-known gene repression marks like methylated lysine 9 in histone H3 (H3K9me) in transcriptionally competent chromatin (6). For example, H4K12bio can be found at the promoter of the gene *SLC5A6* that codes for the transporter mediating biotin uptake into cells, the human sodium-dependent multivitamin transporter (hSMVT). When biotin is abundant, HCS can biotinylate histones H4 in the *SLC5A6* promoter, which down regulates hSMVT synthesis and reduces biotin uptake. Conversely, in biotin-deficient cells, biotinylation marks in the *SLC5A6* promoter are removed increasing gene expression and enabling the synthesis of hSMVT and uptake of biotin (7).

Deficiency

Although clinically overt biotin deficiency is very rare, the human requirement for dietary biotin has been demonstrated in three different situations: prolonged intravenous feeding (parenteral) without biotin supplementation, infants fed an elemental formula devoid of biotin, and consumption of raw egg white for a prolonged period (many weeks to years) (8). Raw egg white contains avidin; this antimicrobial protein binds biotin with an affinity and specificity that is almost unique as a reversible binding. Because native avidin is resistant to mammalian and microbial digestion, avidin prevents biotin absorption. Cooking egg white denatures avidin, rendering it susceptible to digestion and therefore unable to block the absorption of dietary biotin (5).

Signs and symptoms of biotin deficiency

Signs of overt biotin deficiency include hair loss (alopecia) and a scaly red rash around the eyes, nose, mouth, and genital area. Neurologic symptoms in adults have included depression, lethargy, hallucinations, numbness and tingling of the extremities, ataxia, and seizures. The characteristic facial rash, together with unusual facial fat distribution, has been termed the "biotin deficient facies" by some investigators (1). Individuals with hereditary disorders of biotin metabolism (see Inborn metabolic disorders) that result in functional biotin deficiency often have similar physical findings, impaired immune system function, and increased susceptibility to bacterial and fungal infections (9, 10).

Risk factors for biotin deficiency

Aside from prolonged consumption of raw egg white or total intravenous nutritional support lacking biotin, other conditions may increase the risk of biotin depletion. Smoking has been associated with increased biotin catabolism (11). The rapidly dividing cells of the developing fetus require biotin for synthesis of essential carboxylases and for histone biotinylation; hence, the maternal biotin requirement is likely increased during pregnancy. Research suggests that a substantial number of women develop marginal or subclinical biotin deficiency during normal pregnancy (see also Disease Prevention) (8, 12, 13). Moreover, certain types of liver disease may decrease biotinidase activity and theoretically increase the requirement for biotin. For example, a study of 62 children with chronic liver disease and 27 healthy controls found serum biotinidase activity to be abnormally low in those with severely impaired liver function due to cirrhosis (14). However, this study did not provide evidence of biotin deficiency. Additionally, anticonvulsant medications used to prevent seizures in individuals with epilepsy increase the risk of biotin depletion (for more information on biotin and anticonvulsants, see Drug interactions).

Inborn metabolic disorders

Biotinidase deficiency

Biotinidase deficiency is an autosomal recessive inherited disorder that is often detected upon newborn screening for metabolic disorders, although late-onset forms have been recently described (15-17). Biotinidase deficiency leads to secondary biotin deficiency in several ways. Intestinal absorption is decreased because deficient biotinidase impairs release of biotin from dietary protein (18). Further, recycling of intracellular biotin bound to carboxylases and histones is also impaired, and urinary loss of biocytin (*N*-biotinyl-lysine) and biotin is increased (see **Figure 1** above) (5). Biotinidase deficiency responds to supplemental biotin. Oral supplementation with as much as 5 to 20 milligrams (mg) of biotin daily is sometimes required (19, 20), although smaller doses may be sufficient, especially later in childhood (reviewed in 20, 21). Prognosis is characteristically good when biotin therapy is introduced in infancy or early childhood and reliably continued for life (10).

Holocarboxylase synthetase deficiency

Holocarboxylase synthetase deficiency results in decreased formation of all holocarboxylases at physiological blood biotin concentrations; thus, high-dose biotin supplementation (10-80 mg of biotin daily) is required (10). Holocarboxylase synthetase deficiency responds to supplementation with pharmacologic doses of biotin in some cases but not others. The prognosis of holocarboxylase synthetase is usually, but not always, good if biotin therapy is introduced early (even antenatally) and continued for life (10, 22).

Biotin transport deficiency

There has been one case report of a child with biotin transport deficiency who responded to high-dose biotin supplementation (23). Of note, the presence of a defective human sodium-dependent multivitamin transporter (hSMVT) was ruled out as a cause of biotin transport deficiency.

Markers of biotin status

Four measures of marginal biotin deficiency have been validated as indicators of biotin status: and (1) reduced levels of holo-methylcrotonyl-CoA carboxylase and holo-propionyl-CoA carboxylase in lymphocytes, the most reliable indicators of biotin status (24); (2) reduced propionyl-CoA carboxylase activity in peripheral blood lymphocytes (5); (3) high urinary excretion of an organic acid, 3-hydroxyisovaleric acid, and its derivative, 3-hydroxyisovaleryl carnitine, both of which reflect decreased activity of biotin-dependent methylcrotonyl-CoA carboxylase; (4) reduced urinary excretion of biotin and some of its catabolites. These markers have been only validated in men and nonpregnant women, and they may not accurately reflect biotin status in pregnant or breast-feeding women (12, 25).

The Adequate Intake (AI)

Sufficient scientific evidence is lacking to estimate the dietary requirement for biotin; thus, no Recommended Dietary Allowance (RDA) for biotin has been established. Instead, the Food and Nutrition Board of the National Academy of Medicine set recommendations for an Adequate Intake (AI; **Table 1**). The AI for adults (30 μg/day) was extrapolated from the AI for infants exclusively fed human milk and probably overestimates the dietary requirement for biotin for most adults. Dietary intakes of generally healthy adults have been estimated to be 40 to 60 micrograms (μg) of biotin daily (1). The requirement for biotin in pregnancy may be increased (26).

Table 1. Adequate Intake (AI) for Biotin

Life Stage	Age	Males (μg/day)	Females (μg/day)
Infants	0-6 months	5	5
Infants	7-12 months	6	6
Children	1-3 years	8	8
Children	4-8 years	12	12
Children	9-13 years	20	20
Adolescents	14-18 years	25	25
Adults	19 years and older	30	30
Pregnancy	all ages	-	30
Breast-feeding	all ages	-	35

Disease Prevention

Congenital anomalies

Current research indicates that at least one-third of women develop marginal biotin deficiency during pregnancy (8). Small observational studies in pregnant women have reported an abnormally high urinary excretion of 3-hydroxyisovaleric acid in both early and late pregnancy, suggesting decreased activity of biotin-dependent methylcrotonyl-CoA carboxylase (27, 28). In a randomized, single-blinded intervention study in 26 pregnant women, supplementation with 300 μg/day of biotin for two weeks limited the excretion of 3-hydroxyisovaleric acid compared to placebo, confirming that increased 3-hydroxyisovaleric acid excretion indeed reflected marginal biotin deficiency in pregnancy (29). A small cross-sectional study in 22 pregnant women reported an incidence of low lymphocyte propionyl-CoA carboxylase activity greater than 80% (13). Although these levels of biotin deficiency are not associated with overt signs of deficiency in pregnant women, such observations are sources of concern because subclinical biotin deficiency has been shown to cause cleft palate and limb hypoplasia in several animal species (reviewed in 13). In addition, biotin depletion has been found to suppress the expression of biotin-dependent carboxylases, remove biotin marks from histones, and decrease the proliferation in human embryonic palatal mesenchymal cells in culture (30). Impaired carboxylase activity may result in alterations in lipid metabolism, which have been linked to cleft palate and skeletal abnormalities in animals. Further, biotin deficiency leading to reduced histone biotinylation at specific genomic loci may increase genomic instability and result in chromosome anomalies and fetal malformations (13).

Analogous to pregnant women who are advised to consume supplemental folic acid prior to and during pregnancy to prevent neural tube defects (see Folate), it would also be prudent to ensure adequate biotin intake throughout pregnancy. The current AI for pregnant women is 30 μg/day of biotin, and no toxicity has ever been reported at this level of intake (see Safety).

Disease Treatment

Biotin-thiamin-responsive basal ganglia disease

Biotin-thiamin-responsive basal ganglia disease (also called biotin-responsive basal ganglia disease, thiamin transporter-2 deficiency, and thiamin metabolism dysfunction syndrome-2) is caused by an autosomal recessive mutation in the *SLC19A3* gene that codes for thiamin transporter-2 (THTR-2). The disease usually presents around 3 to 10 years of age (31), but an early infantile form of the disease exists with onset as early as one month of age (32). Clinical features include subacute encephalopathy (confusion, drowsiness, altered level of consciousness), ataxia, and seizures.

A retrospective study of 18 affected individuals from the same family or the same tribe in Saudi Arabia showed that biotin monotherapy (5-10 mg/kg/day) efficiently abolished the clinical manifestations of the disease, although one-third of the patients suffered from recurrent acute crises. Often associated with poor outcomes, acute crises were not observed after thiamin supplementation started (300-400 mg/day) and during a five-year follow-up period, early diagnosis and immediate treatment with biotin and thiamin led to positive outcomes (33). Although the specific mechanism for therapeutic effects of biotin in biotin-thiamin-responsive basal ganglia disease remains unknown, lifelong high-dose supplementation with a combination of biotin and thiamin is the recommended treatment (31). Early diagnosis and treatment is important to ensure a better prognosis (32, 34).

Multiple sclerosis

Multiple sclerosis (MS) is an autoimmune disease characterized by progressive damage to the myelin sheath surrounding nerve fibers (axons) and neuronal loss in the brain and spinal cord of affected individuals in anatomic locations that vary widely among affected individuals producing variable signs and symptoms. The progression of neurologic disabilities in MS patients is often assessed by the Expanded Disability Status Scale (EDSS) with scores from 1 to 10, from minimal signs of motor dysfunction (score of 1) to death by MS (score of 10). ATP deficiency due to mitochondrial dysfunction and increased oxidative stress may be partly responsible for the progressive degeneration of neurons in MS (35). Given its role in energy production by intermediary metabolism and fatty acid oxidation and in fatty acid synthesis (required for myelin formation) (see Function), high-dose biotin supplementation it has been hypothesized that to exert beneficial effects that would limit or reverse MS-associated functional impairments (35).

The mechanism of action of high-dose biotin has been investigated in a genetic mouse model of chronic axon injury caused by oxidative damage and bioenergetic failure. High-dose biotin restored redox homeostasis, mitochondria biogenesis, and ATP levels, and reversed axonal death and locomotor impairment. Dysregulation of the transcriptional program for lipid synthesis and degradation in the spinal cord was also normalized, possibly as the result of hyperactivation of a nutrient/energy/redox sensor that controls protein synthesis restoring lipid homeostasis.

A nonrandomized, uncontrolled pilot study in 23 patients with progressive MS found high doses of biotin (100-600 mg/day) to be associated with sustained clinical improvements in five (out of five) patients with progressive visual loss and 16 (out of 18) patients with partial paralysis of the limbs after a mean three months following treatment onset (36). Additionally, a multicenter, randomized, placebo-controlled trial in 154 subjects with progressive MS reported that 13 out of 103 patients supplemented with high-dose, pharmaceutical-grade biotin (300 mg/day) for 12 months achieved MS-related disability reversal — assessed by improved EDSS or 25-foot walk time (37). In comparison, none of the 51 patients randomized to the placebo group showed significant clinical improvements (37). However, when this regimen of high-dose biotin supplementation was examined in a larger, international cohort of patients with progressive MS (326 patients receiving biotin and 316 patients receiving placebo), no benefits on EDSS or walk time were seen after 12 months (38). Moreover, a randomized, double-blind, placebo-controlled trial in 93 MS patients with chronic visual loss found that 300 mg/day of pharmaceutical-grade biotin for six months did not improve visual acuity, but an interesting trend favoring the biotin group was observed in the subgroup of patients with progressive optic neuritis (39). Moreover, a meta-analysis of three randomized controlled trials (2 on disability; 3 on adverse effects), involving 889 individuals diagnosed with MS (the preponderance of participants [830] had progressive MS while only 59 had remitting relapsing MS) was conducted (40). Pooling results of two trials found no benefit of high-dose biotin on MS-related disability, but there was significant heterogeneity between the trials. When the subgroup progressive MS was analyzed separately, a moderate certainty of evidence suggested a potential benefit in favor of high-dose biotin for the 25-foot minute walk time (40). On balance, studies remain inconclusive but promising.

Diabetes mellitus

Overt biotin deficiency has been shown to impair glucose utilization in mice (41) and cause fatal hypoglycemia in chickens. Overt biotin deficiency likely also causes abnormalities in glucose regulation in humans (see Function). One early human study reported lower serum biotin concentrations in 43 patients with type 2 diabetes mellitus compared to 64 control subjects without the disease; an inverse relationship between fasting blood glucose and biotin concentrations was observed as well (42). In a small, randomized, placebo-controlled intervention study in 28 patients with type 2 diabetes, daily supplementation with 9 milligrams (mg) of biotin for one month resulted in a 45% decrease in mean fasting blood glucose concentrations (42). Yet, another small study in 10 patients with type 2 diabetes and 7 controls without diabetes found no effect of biotin supplementation (15 mg/day) for 28 days on fasting blood glucose concentrations in either group (43). A more recent double-blind, placebo-controlled study by the same research group showed that the same biotin regimen lowered plasma triglyceride concentrations in patients with hypertriglyceridemia — independent of whether they had type 2 diabetes (44). In this study, biotin administration did not affect blood glucose concentrations in either patient group. Additionally, a few studies have shown that co-supplementation with biotin and chromium picolinate may be a beneficial adjunct therapy in patients with type 2 diabetes (45-48). For information on chromium supplementation as a monotherapy for type 2 diabetes, see the article on Chromium.

Potential mechanisms for the glucose and lipid effects have been suggested. As a cofactor of carboxylases required for fatty acid synthesis, biotin may increase the utilization of glucose for fat synthesis. Also, biotin stimulates glucokinase, a liver enzyme that increases synthesis of glycogen, the storage form of glucose. Biotin also triggers the secretion of insulin in the pancreas of rats and improves glucose homeostasis (50). Yet, reduced activity of ACC1 and ACC2 would be expected to reduce fatty acid synthesis and increase fatty acid oxidation, respectively. Hence, whether pharmacologic doses of biotin benefits the management of hyperglycemia in patients with impaired glucose tolerance remains unclear. Moreover, whether supplemental biotin lowers the risk of cardiovascular complications in patients with diabetes by reducing serum triglycerides and LDL-cholesterol remains to be proven (44-46).

Brittle fingernails (onychorrhexis)

The finding that biotin supplements were effective in treating hoof abnormalities in hoofed animals suggested that biotin might also be helpful in strengthening brittle fingernails in humans (50-52). Three uncontrolled trials examining the effects of biotin supplementation (2.5 mg/day for several months) in women with brittle fingernails have been published (53-55). In two of the trials, subjective evidence of clinical improvement was reported in 67%-91% of the participants available for follow-up at the end of the treatment period (53, 54). One trial that used scanning electron microscopy to assess fingernail brittleness reported less fingernail splitting and a 25% increase in the thickness of the nail plate in patients supplemented with biotin for 6 to 15 months (55). Biotin supplementation (5 mg/day) was also found to be effective in controlling unruly hair and splitting nails in two toddlers with inherited uncombable hair syndrome (56). Although preliminary evidence suggests that supplemental biotin may help strengthen fragile nails (reviewed in 57), larger placebo-controlled trials are needed to assess the efficacy of high-dose biotin supplementation for the treatment of brittle fingernails.

Hair loss (alopecia)

Biotin administration has been associated with alopecia reversal in children treated with the anticonvulsant valproic acid (see Drug interactions), as well as with hair regrowth or normal hair growth in some children with inborn errors of biotin metabolism or other genetic disorders (i.e., uncombable hair syndrome) (reviewed in 58). Yet, while hair loss is a symptom of severe biotin deficiency (see Deficiency), there are no published scientific studies that support the claim that high-dose biotin supplements are effective in preventing or treating hair loss in men or women (59, 60). Randomized, placebo-controlled trials in healthy individuals would be needed to evaluate this claim.

Sources

Food sources

Biotin is found in many foods, either as the free (i.e., unbound) form that is directly taken up by enterocytes or as biotin bound to dietary proteins. Egg yolk, liver, and yeast are rich sources of biotin. Estimates of average daily intakes of biotin from small studies ranged between 40 and 60 micrograms (μg) per day in adults (1). However, US national nutritional surveys have not yet been able to estimate biotin intake due to the scarcity and unreliability of data regarding biotin content of food. Food composition tables for biotin are incomplete such that dietary intakes cannot be reliably estimated in humans. A study by Staggs et al. (61) employed a high-performance liquid chromatography method rather than bioassays (62) and reported relatively different biotin content for some selected foods. **Table 2** lists some food sources of biotin, along with their content in μg.

Table 2. Some Food Sources of Biotin (61, 62)

Food	Serving	Biotin (μg)
Yeast	1 packet (7 grams)	1.4-14
Bread, whole-wheat	1 slice	0.02-6
Egg, cooked	1 large	13-25
Cheese, cheddar	1 ounce	0.4-2
Liver, cooked	3 ounces*	27-35
Pork, cooked	3 ounces*	2-4
Salmon, cooked	3 ounces*	4-5
Avocado	1 whole	2-6
Raspberries	1 cup	0.2-2
Cauliflower, raw	1 cup	0.2-4
*A three-ounce serving of meat is about the size of a deck of cards.		

Bacterial synthesis

A majority of bacteria that normally colonize the small and large intestine (colon) synthesize biotin (63). Whether the biotin is released and absorbed by humans in meaningful amounts remains unknown. The uptake of free biotin into intestinal cells via the human sodium-dependent multivitamin transporter (hSMVT) has been identified in cultured cells derived from the lining of the small intestine and colon (64), suggesting that humans may be able to absorb biotin produced by enteric bacteria — a phenomenon documented in swine.

Supplements

Biotin is available as a single-nutrient supplement in various doses (many containing 5,000 μg [5 mg] of biotin) and is often included in B-complex and multivitamin-mineral supplements. Several multivitamin supplements contain 30 μg of biotin, although the amount varies by product (65).

Safety

Toxicity

Biotin is not known to be toxic. In people without disorders of biotin metabolism, doses of up to 5 mg/day (5,000 μg) for two years were not associated with adverse effects (66). Oral biotin supplementation has been well tolerated in doses up to 200 mg/day (nearly 7,000 times the AI) in people with hereditary disorders of biotin metabolism (1). Daily supplementation with a highly concentrated formulation of biotin (100-600 mg) for several months was also found to be well tolerated in individuals with progressive multiple sclerosis (36, 67). However, there is one case report of life-threatening eosinophilic pleuropericardial effusion in an elderly woman who took a combination of 10 mg/day of biotin and 300 mg/day of pantothenic acid (vitamin B$_5$) for two months (68). Because reports of adverse events were lacking when the Dietary Reference Intakes (DRIs) for biotin were established in 1998, the Food and Nutrition Board did not establish a tolerable upper intake level (UL) for biotin (1).

Nutrient interactions

Large doses of pantothenic acid (vitamin B$_5$) have the potential to compete with biotin for intestinal and cellular uptake by the human sodium-dependent multivitamin transporter (hSMVT) (69, 70). Biotin also shares the hSMVT with lipoic acid (71). Pharmacologic (very high) doses of lipoic acid have been found to decrease the activity of biotin-dependent carboxylases in rats, but such an effect has not been demonstrated in humans (72).

Drug interactions

Individuals on long-term anticonvulsant (anti-seizure) therapy reportedly have reduced blood biotin concentrations, as well as an increased urinary excretion of organic acids (e.g., 3-hydroxyisovaleric acid) that indicate decreased carboxylase activity (see Markers of biotin status) (5). Potential mechanisms of biotin depletion by the anticonvulsants, primidone (Mysoline), phenytoin (Dilantin, Phenytek), and carbamazepine (Carbatrol, Epitol, Equetro, Tegretol), include inhibition of biotin intestinal absorption and renal reabsorption, as well as increased biotin catabolism (73). Use of the anticonvulsant valproic acid in children has resulted in hair loss reversed by biotin supplementation (74-77). Long-term treatment with antibacterial sulfonamide (sulfa) drugs or other antibiotics may decrease bacterial synthesis of biotin. Yet, given that the extent to which bacterial synthesis contributes to biotin intake in humans is not known, effects of antimicrobial drugs on biotin nutritional status remain uncertain (73).

Interference with lab assays

In 2017, the US Food and Drug Administration (FDA) released a safety communication regarding high-dose biotin supplementation and its potential interference with streptavidin (avidin)-biotin immunoassays, including assays of thyroid hormones, reproductive hormones, and the cardiac protein, troponin. Such interference can cause aberrant results — either falsely high or falsely low depending on the method of the particular assay — and potential misdiagnosis of disease (78-81). An updated FDA communication in 2019 focused on biotin interference in certain lab assays of troponin that have not addressed the concern of falsely low blood concentrations (82). Troponin in blood is a marker of cardiac damage and often used in the clinical diagnosis of a myocardial infarction (heart attack). When blood work is planned, patients should routinely inform their health care provider concerning supplementation of biotin at doses substantially greater than those in usual diets or in routine daily multivitamins.

Linus Pauling Institute Recommendation

Little is known regarding the amount of dietary biotin required to promote optimal health or prevent chronic disease. The Linus Pauling Institute supports the recommendation made by the National Academy of Medicine, which is 30 micrograms (μg) of biotin per day for adults. A varied diet should provide enough biotin for most people. However, following the Linus Pauling Institute recommendation to take a daily multivitamin-mineral supplement will generally provide an intake of at least 30 μg/day of biotin.

Older adults (>50 years)

Presently, there is no indication that older adults have an increased requirement for biotin. If dietary biotin intake is not sufficient, a daily multivitamin-mineral supplement will generally provide an intake of at least 30 μg of biotin per day.

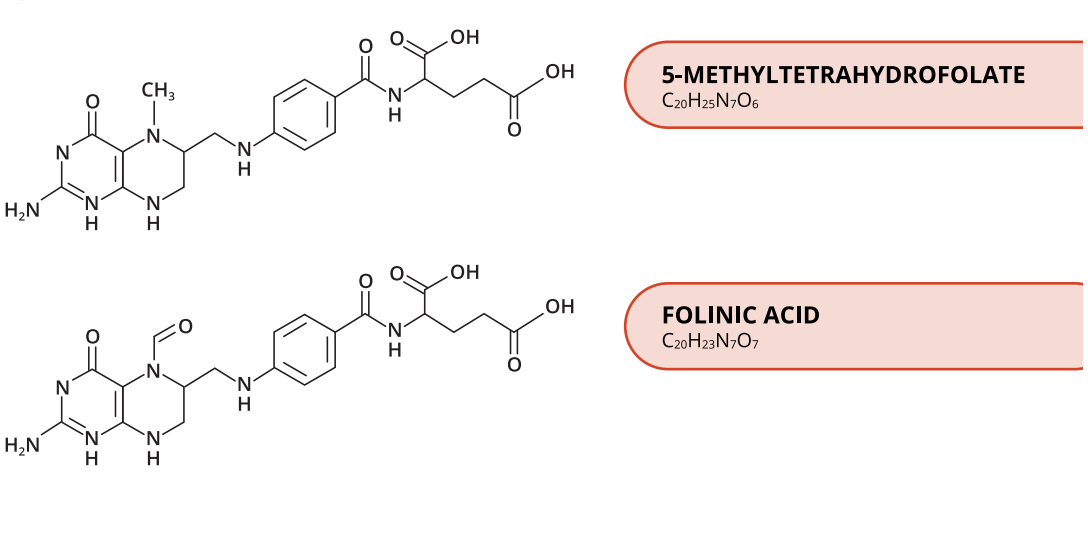
Summary

- Folate is a generic term referring to both natural folates in food and folic acid, the synthetic form used in supplements and fortified food. Folate is critical in the metabolism of nucleic acid precursors and several amino acids, as well as in methylation reactions. *(More information)*
- Severe deficiency in either folate or vitamin B_{12} can lead to megaloblastic anemia, which causes fatigue, weakness, and shortness of breath. Improper treatment of vitamin B_{12}-dependent megaloblastic anemia with high dose supplemental folic acid can potentially delay the diagnosis of vitamin B_{12} deficiency and thus leave the individual at risk of developing irreversible brain damage. *(More information)*
- Folate status is influenced by the presence of genetic variations in folate metabolism, particularly those found in the 5,10-methylenetetrahydrofolate reductase (*MTHFR*) gene. *(More information)*
- Inadequate folate status during early pregnancy increases the risk of congenital anomalies. The introduction of mandatory folic acid fortification of refined grain products in the US in 1998 has reduced the prevalence of neural tube defects (NTDs) in newborns. Yet, folate status is considered inadequate in a majority of women of childbearing age worldwide. Moreover, genetic factors might modify the risk of NTDs by increasing the susceptibility to folate deficiency during pregnancy. Several studies are currently investigating the role of folic acid supplementation in the prevention of congenital anomalies other than NTDs. *(More information)*
- Folate deficiency and elevated concentrations of homocysteine in the blood are associated with increased risk of cardiovascular disease (CVD). Although folic acid supplementation has been proven effective to control circulating homocysteine concentrations, the effect of homocysteine lowering on the incidence of CVD is still debated. *(More information)*
- Low folate status has been linked to increased cancer risk. However, intervention trials with high doses of folic acid have not generally shown any benefit on cancer incidence. *(More information)*
- Prospective cohort studies have reported an inverse association between folate status and colorectal cancer (CRC) risk, especially among men. The relationship between folate status and cancer risk is however complex and requires further research. *(More information)*
- Folate is essential for brain development and function. Low folate status and/or high homocysteine concentrations are associated with cognitive dysfunction in aging (from mild impairments to dementia). Whether supplemental B-vitamins, including folic acid, will have long-term benefits in maintaining cognitive health is not yet known. *(More information)*
- Several autosomal recessive disorders affecting folate transport and metabolism can be treated with high doses of folinic acid, a folate derivative. *(More information)*

Folate is a water-soluble B-vitamin, which is also known as vitamin B_9 or folacin. Naturally occurring folates exist in many chemical forms; folates are found in food, as well as in metabolically active forms in the human body. Folic acid is the major synthetic form found in fortified foods and vitamin supplements. Other synthetic forms include folinic acid (**Figure 1**) and levomefolic acid. Folic acid has no biological activity unless converted into folates (1). In the following discussion, forms found in food or the body are referred to as "folates," while the form found in supplements or fortified food is referred to as "folic acid."

Figure 1. Chemical Structures

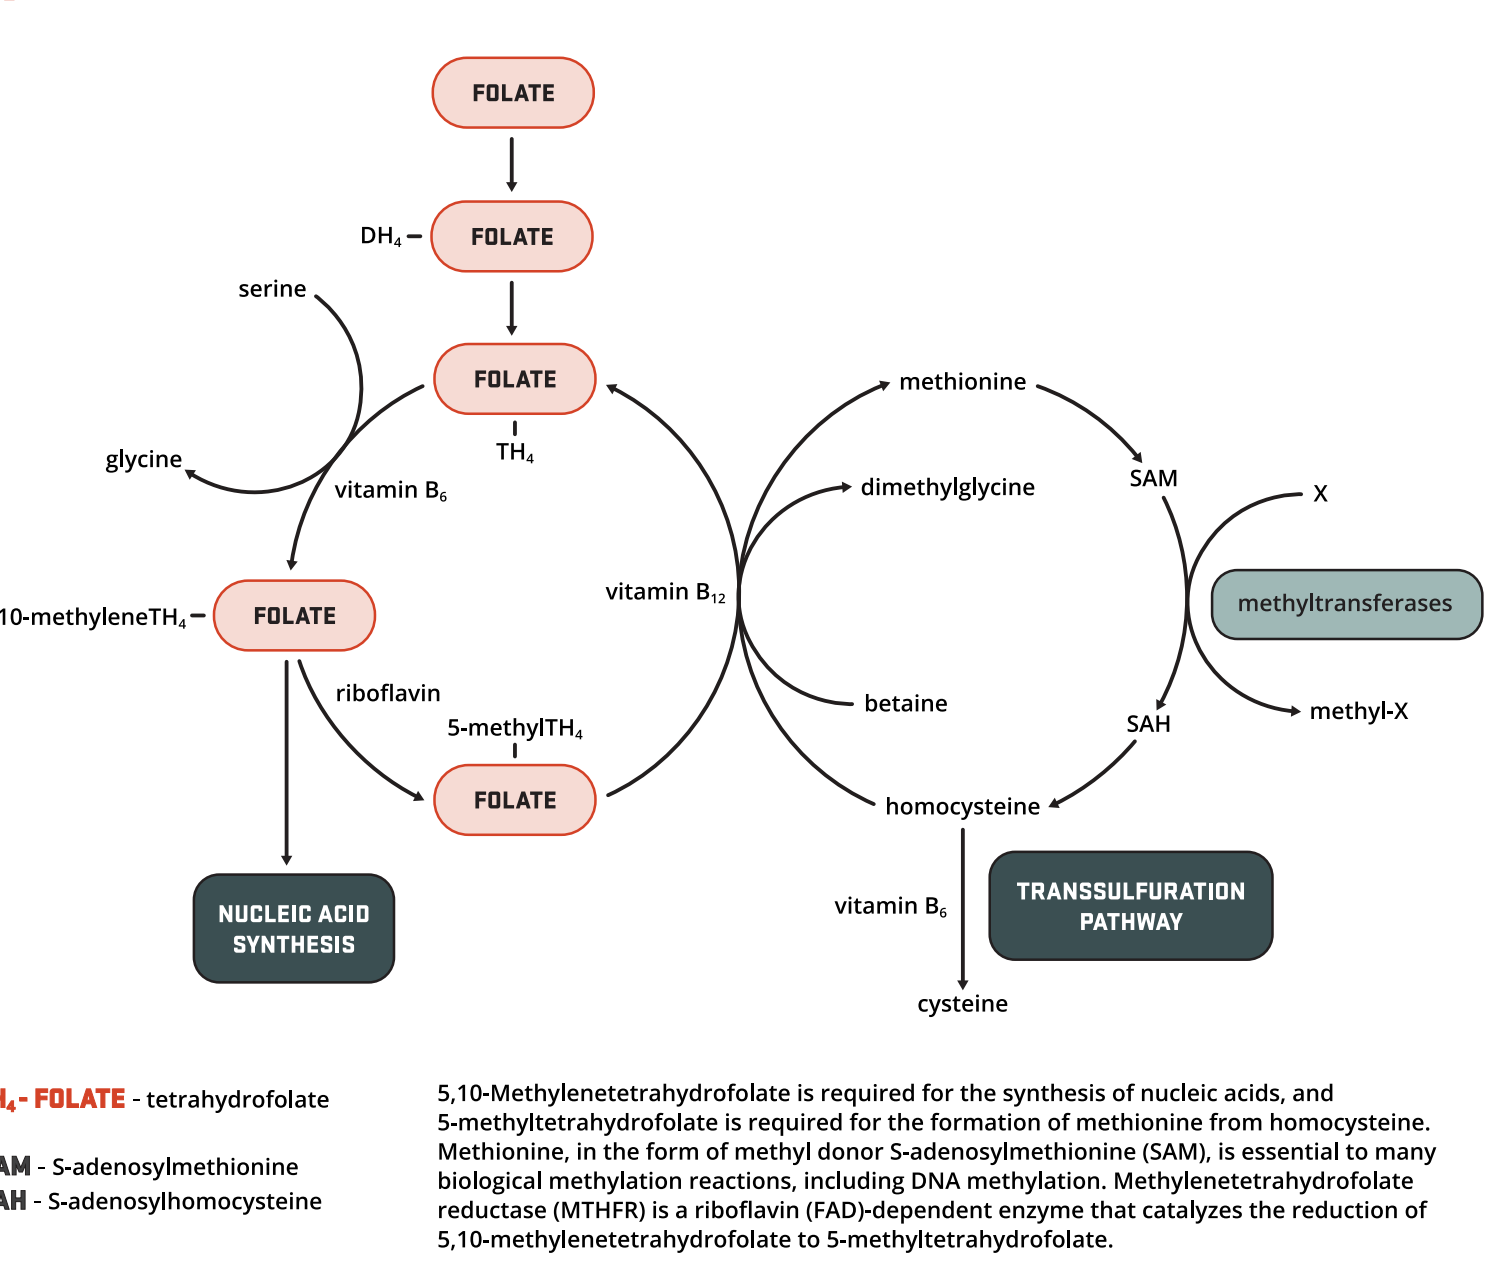


Function

One-carbon metabolism

The only function of folate coenzymes in the body appears to be in mediating the transfer of one-carbon units (2). Folate coenzymes act as acceptors and donors of one-carbon units in a variety of reactions critical to the metabolism of nucleic acids and amino acids (**Figure 2**) (3).

Figure 2. Overview of One-carbon Metabolism



5,10-Methylenetetrahydrofolate is required for the synthesis of nucleic acids, and 5-methyltetrahydrofolate is required for the formation of methionine from homocysteine. Methionine, in the form of methyl donor S-adenosylmethionine (SAM), is essential to many biological methylation reactions, including DNA methylation. Methylenetetrahydrofolate reductase (MTHFR) is a riboflavin (FAD)-dependent enzyme that catalyzes the reduction of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate.

Nucleic acid metabolism

Folate coenzymes play a vital role in DNA metabolism through two different pathways. (1) The synthesis of DNA from its precursors (thymidine and purines) is dependent on folate coenzymes. (2) A folate coenzyme is required for the synthesis of methionine from homocysteine, and methionine is required for the synthesis of S-adenosylmethionine (SAM). SAM is a methyl group (one-carbon unit) donor used in most biological methylation reactions, including the methylation of a number of sites within DNA, RNA, proteins, and phospholipids. The methylation of DNA plays a role in controlling gene expression and is critical during cell differentiation. Aberrations in DNA methylation have been linked to the development of cancer (see Cancer).

Amino acid metabolism

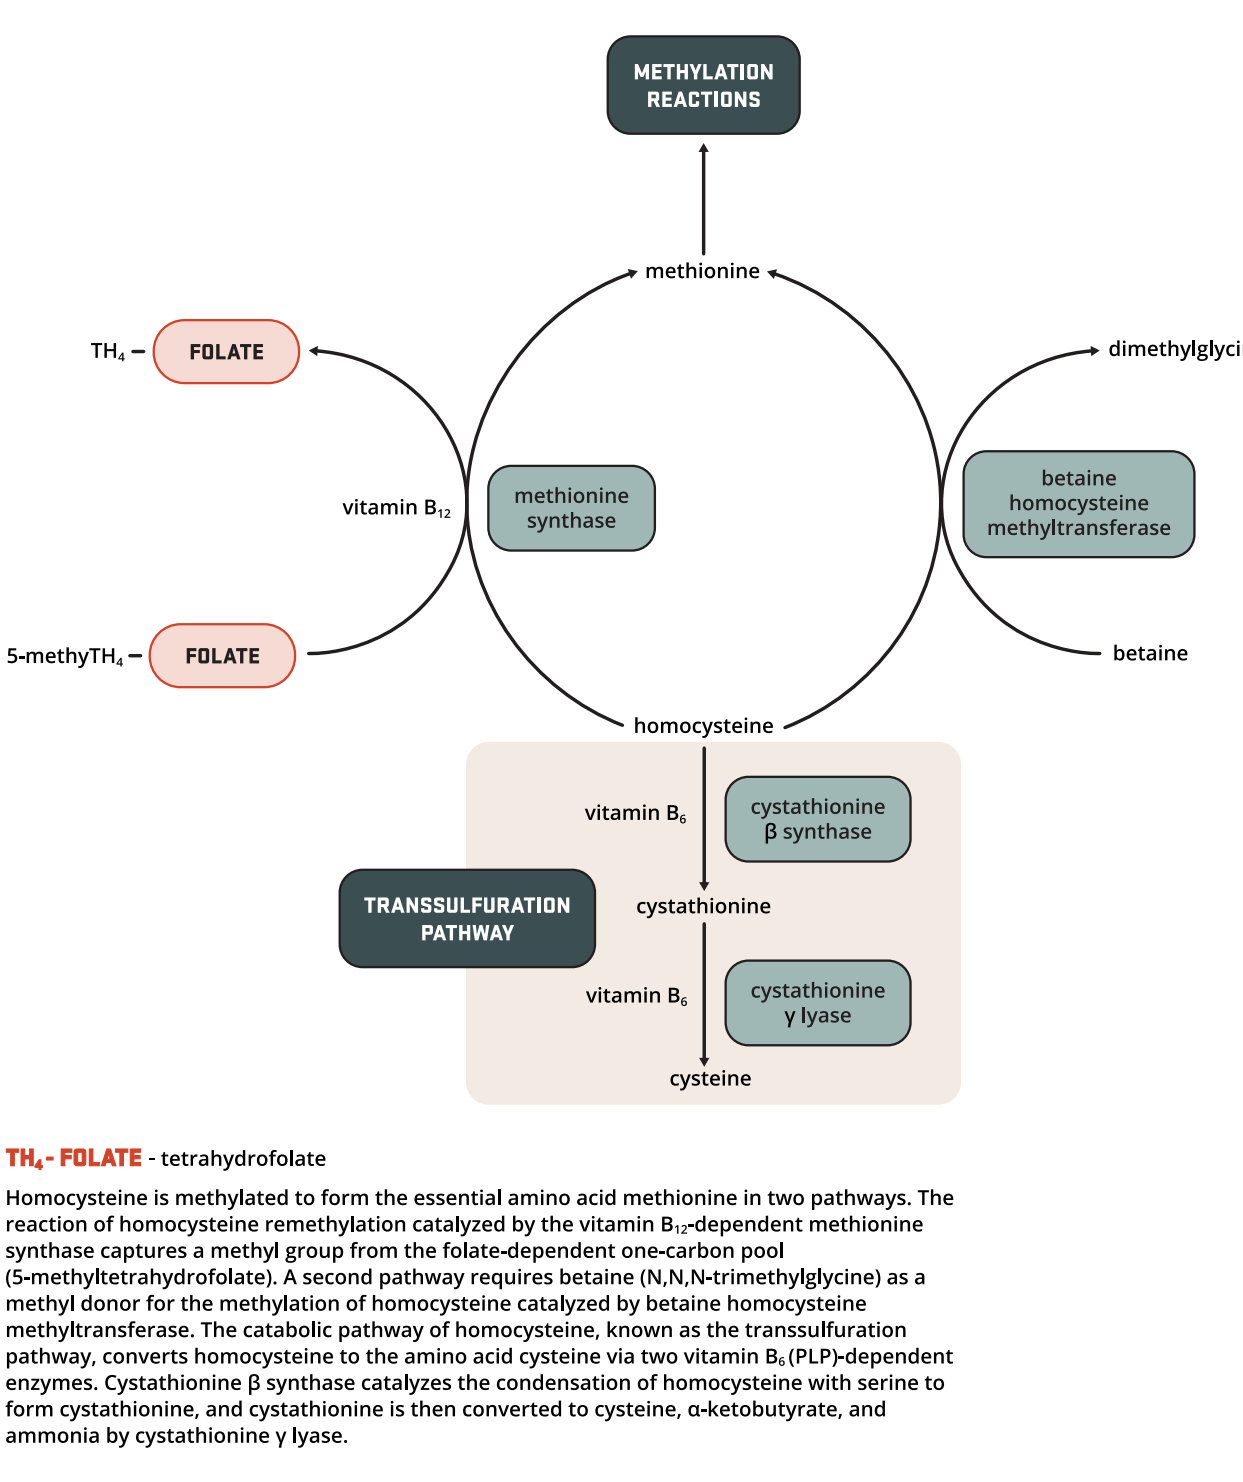
Folate coenzymes are required for the metabolism of several important amino acids, namely methionine, cysteine, serine, glycine, and histidine. The synthesis of methionine from homocysteine is catalyzed by methionine synthase, an enzyme that requires not only folate (as 5-methyltetrahydrofolate) but also vitamin B_{12}. Thus, folate (and/or vitamin B_{12}) deficiency can result in decreased synthesis of methionine and an accumulation of homocysteine. Elevated blood concentrations of homocysteine have been considered for many years to be a risk factor for some chronic diseases, including cardiovascular disease and dementia (see Disease Prevention).

Nutrient interactions

Vitamin B_{12} and vitamin B_6

The metabolism of homocysteine, an intermediate in the metabolism of sulfur-containing amino acids, provides an example of the interrelationships among nutrients necessary for optimal physiological function and health. Healthy individuals utilize two different pathways to metabolize homocysteine (**Figure 3**). One pathway (methionine synthase) synthesizes methionine from homocysteine and is dependent on both folate and vitamin B_{12} as cofactors. The other pathway converts homocysteine to another amino acid, cysteine, and requires two vitamin B_6-dependent enzymes. Thus, the concentration of homocysteine in the blood is regulated by three B-vitamins: folate, vitamin B_{12}, and vitamin B_6 (4). In some individuals, riboflavin (vitamin B_2) is also involved in the regulation of homocysteine concentrations (see the article on Riboflavin).

Figure 3. Homocysteine Metabolism



Homocysteine is methylated to form the essential amino acid methionine in two pathways. The reaction of homocysteine remethylation catalyzed by the vitamin B_{12}-dependent methionine synthase captures a methyl group from the folate-dependent one-carbon pool (5-methyltetrahydrofolate). A second pathway requires betaine (N,N,N-trimethylglycine) as a methyl donor for the methylation of homocysteine catalyzed by betaine homocysteine methyltransferase. The catabolic pathway of homocysteine, known as the transsulfuration pathway, converts homocysteine to the amino acid cysteine via two vitamin B_6 (PLP)-dependent enzymes. Cystathionine β synthase catalyzes the condensation of homocysteine with serine to form cystathionine, and cystathionine is then converted to cysteine, α-ketobutyrate, and ammonia by cystathionine γ lyase.

Riboflavin

Although less well recognized, folate has an important metabolic interaction with riboflavin. Riboflavin is a precursor of flavin adenine dinucleotide (FAD), a coenzyme required for the activity of the folate-metabolizing enzyme, 5,10-methylenetetrahydrofolate reductase (MTHFR). FAD-dependent MTHFR in turn catalyzes the reaction that generates 5-methyltetrahydrofolate (see **Figure 2** above). This active form of folate is required to form methionine from homocysteine. Along with other B-vitamins, higher riboflavin intakes have been associated with decreased plasma homocysteine concentrations (5). The effects of riboflavin on folate metabolism appear to be greatest in individuals homozygous for the common c.677C>T polymorphism (i.e., TT genotype) in the *MTHFR* gene (see Genetic variation in folate requirements) (6). These individuals (about 10% of adults worldwide) typically present with low folate status, along with elevated homocysteine concentrations, particularly when folate and/or riboflavin intake is suboptimal. The elevated homocysteine concentration in these individuals, however, is highly responsive to lowering with riboflavin supplementation, confirming the importance of the riboflavin-*MTHFR* interaction (7).

Vitamin C

Vitamin C may limit degradation of natural folate coenzymes and supplemental folic acid in the stomach and thus improve folate bioavailability. A cross-over trial in nine healthy men found that oral co-administration of 5-methyltetrahydrofolic acid (343 μg) and vitamin C (289 mg or 974 mg) was associated with higher concentrations of serum folate compared to 5-methyltetrahydrofolic acid alone (8). Moreover, a recent study suggested that several genetic variations of folate metabolism might influence the effect of vitamin C on folate metabolism (9).

Bioavailability

Dietary folates exist predominantly in the polyglutamyl form (containing several glutamate residues), whereas folic acid—the synthetic vitamin form—is a monoglutamate, containing just one glutamate moiety. In addition, natural folates are reduced molecules, whereas folic acid is fully oxidized. These chemical differences have major implications for the bioavailability of the vitamin such that folic acid is considerably more bioavailable than naturally occurring food folates at equivalent intake levels.

The intestinal absorption of dietary folates is a two-step process that involves the hydrolysis of folate polyglutamates to the corresponding monoglutamyl derivatives, followed by their transport into intestinal cells. There, folic acid is converted into a naturally occurring folate, namely 5-methyltetrahydrofolate, which is the major circulating form of folate in the human body (see **Figure 1** above).

The bioavailability of naturally occurring folates is inherently limited and variable. There is much variability in the ease with which folates are released from different food matrices, and the polyglutamyl "tail" is removed (de-conjugation) before uptake by intestinal cells. Also, other dietary constituents can contribute to instability of labile folates during the processes of digestion. As a result, naturally occurring folates show incomplete bioavailability compared with folic acid. The bioavailability of folic acid, in contrast, is assumed to be 100% when ingested as a supplement, while folic acid in fortified food is estimated to have about 85% the bioavailability of supplemental folic acid.

Of note, folate recommendations in the US and certain other countries are now expressed as Dietary Folate Equivalents (DFEs), a calculation that was devised to take into account the greater bioavailability of folic acid compared to naturally occurring dietary folates (see The Recommended Dietary Allowance).

Transport

Folate and its coenzymes require transporters to cross cell membranes. Folate transporters include the reduced folate carrier (RFC), the proton-coupled folate transporter (PCFT), and the folate receptor proteins, FRα and FRβ. Folate homeostasis is supported by the ubiquitous distribution of folate transporters, although abundance and importance vary among tissues (10). PCFT plays a major role in folate intestinal transport since mutations affecting the gene encoding PCFT cause hereditary folate malabsorption. Defective PCFT also leads to impaired folate transport into the brain (see Disease Treatment). FRα and RFC are also critical for folate transport across the blood-brain barrier when extracellular folate is either low or high, respectively. Folate is essential for the proper development of the embryo and the fetus. The placenta is known to concentrate folate to the fetal circulation, leading to higher folate concentrations in the fetus compared to those found in the pregnant woman. All three types of receptors have been associated with folate transport across the placenta during pregnancy (11).

Deficiency

Causes

Folate deficiency is most often caused by a dietary insufficiency; however, folate deficiency can also occur in a number of other situations. For example, chronic and heavy alcohol consumption is associated with diminished absorption of folate (in addition to low dietary intake), which can lead to folate deficiency (12). Smoking is also associated with low folate status. In one study, folate concentrations in blood were about 15% lower in smokers compared to nonsmokers (13). Additionally, impaired folate transport to the fetus has been described in pregnant women who either smoked or abused alcohol during their pregnancy (14, 15).

Pregnancy is a time when the folate requirement is greatly increased to sustain the demand for rapid cell replication and growth of fetal, placental, and maternal tissue. Conditions such as cancer or inflammation can also result in increased rates of cell division and metabolism, causing an increase in the body's demand for folate (16). Moreover, folate deficiency can result from some malabsorptive conditions, including inflammatory bowel diseases (Crohn's disease and ulcerative colitis) and celiac disease (17). Several medications may also contribute to folate deficiency (see Drug interactions). Finally, a number of genetic diseases affecting folate absorption, transport, or metabolism can cause folate deficiency or impede its metabolic functions (see Disease Treatment).

Symptoms

Clinical folate deficiency leads to megaloblastic anemia, which is reversible with folic acid treatment. Rapidly dividing cells like those derived from bone marrow are most vulnerable to the effects of folate deficiency since DNA synthesis and cell division are dependent on folate coenzymes. When folate supply to the rapidly dividing cells of the bone marrow is inadequate, blood cell division is reduced, resulting in fewer but larger red blood cells. This type of anemia is called megaloblastic or macrocytic anemia, referring to the enlarged, immature red blood cells. Neutrophils, a type of white blood cell, become hypersegmented, a change that can be found by examining a blood sample microscopically. Because normal red blood cells have a lifetime in the circulation of approximately four months, it can take months for folate-deficient individuals to develop the characteristic megaloblastic anemia. Progression of such an anemia leads to a decreased oxygen carrying capacity of the blood and may ultimately result in symptoms of fatigue, weakness, and shortness of breath (1). It is important to point out that megaloblastic anemia resulting from folate deficiency is identical to the megaloblastic anemia resulting from vitamin B_{12} deficiency, and further clinical testing is required to diagnose the true cause of megaloblastic anemia (see Toxicity).

Individuals in the early stages of folate deficiency may not show obvious symptoms, but blood concentrations of homocysteine may increase (see Disease Prevention). Yet, the concentration of circulating homocysteine is not a specific indicator of folate status, as elevated homocysteine can be the result of vitamin B_{12} and other B-vitamin deficiencies, lifestyle factors, and renal insufficiency. Subclinical deficiency is typically detected by measurement of folate concentrations in serum/plasma or in red blood cells.

The Recommended Dietary Allowance (RDA)

Determination of the RDA

Traditionally, the dietary folate requirement was defined as the amount needed to prevent a deficiency severe enough to cause symptoms like anemia. The most recent RDA (1998; **Table 1**) was based primarily on the adequacy of red blood cell folate concentrations at different levels of folate intake, as judged by the absence of abnormal hematological indicators. Red cell folate has been shown to correlate with liver folate stores and is used as an indicator of long-term folate status. Plasma folate reflects recent folate intake and is not a reliable biomarker for folate status. Maintenance of normal blood homocysteine concentrations, an indicator of one-carbon metabolism, was considered only as an ancillary indicator of adequate folate intake.

Because pregnancy is associated with a significant increase in cell division and other metabolic processes that require folate coenzymes, the RDA for pregnant women is considerably higher than for women who are not pregnant (3). However, the prevention of neural tube defects (NTDs) was not considered when setting the RDA for pregnant women. Rather, reducing the risk of NTDs was considered in a separate recommendation for women capable of becoming pregnant (see Disease Prevention), because the crucial events in the development of the neural tube occur before many women are aware that they are pregnant (18).

Dietary Folate Equivalents (DFEs)

When the Food and Nutrition Board of the US Institute of Medicine set the new dietary recommendation for folate, they introduced a new unit, the Dietary Folate Equivalent (DFE) (1). Use of the DFE reflects the higher bioavailability of synthetic folic acid found in supplements and fortified food compared to that of naturally occurring food folates (18).

- 1 microgram (μg) of food folate provides 1 μg of DFEs
- 1 μg of folic acid taken with meals or as fortified food provides 1.7 μg of DFEs
- 1 μg of folic acid (supplement) taken on an empty stomach provides 2 μg of DFEs

For example, a serving of food containing 60 μg of folate would provide 60 μg of DFEs, while a serving of pasta fortified with 60 μg of folic acid would provide 1.7 x 60 = 102 μg of DFEs due to the higher bioavailability of folic acid. A folic acid supplement of 400 μg taken on an empty stomach would provide 800 μg of DFEs. It should be noted that DFEs were determined in studies with adults and whether folic acid in infant formula is more bioavailable than folates in mother's milk has not been studied. Use of DFEs to determine a folate requirement for the infant would not be desirable.

Table 1. Recommended Dietary Allowance for Folate in Dietary Folate Equivalents (DFEs)

Life Stage	Age	Males (μg/day)	Females (μg/day)
Infants	0-6 months	65 (AI)	65 (AI)
Infants	7-12 months	80 (AI)	80 (AI)
Children	1-3 years	150	150
Children	4-8 years	200	200
Children	9-13 years	300	300
Adolescents	14-18 years	400	400
Adults	19 years and older	400	400
Pregnancy	all ages	-	600
Breast-feeding	all ages	-	500

Genetic variation in folate requirements

A common polymorphism or variation in the sequence of the gene for the enzyme, 5, 10-methylenetetrahydrofolate reductase (MTHFR), known as the *MTHFR* c.677C>T polymorphism, results in a thermolabile enzyme (19). The substitution of a cytosine (C) by a thymine (T) at nucleotide 677 in the exon 4 of *MTHFR* gene leads to an alanine-to-valine transition in the catalytic domain of the enzyme. Depending on the population, 20% to 53% of individuals may have inherited one T copy (677C/T genotype), and 3% to 32% of individuals may have inherited two T copies (677T/T genotype) for the *MTHFR* gene (20). MTHFR catalyzes the reduction of 5,10-methylenetetrahydrofolate (5,10-methylene THF) into 5-methyl tetrahydrofolate (5-MeTHF). The latter is the folate coenzyme required to form methionine from homocysteine (see **Figure 2** above). MTHFR activity is greatly diminished in heterozygous 677C/T (-30%) and homozygous 677T/T (-65%) individuals compared to those with the 677C/C genotype (21). Homozygosity for the mutation (677T/T) is linked to lower concentrations of folate in red blood cells and higher blood concentrations of homocysteine (22, 23). Improving folate nutritional status in elderly women with the T allele reduced plasma homocysteine concentration (24). An important unanswered question about folate is whether the present RDA is enough to compensate for the reduced MTHFR enzyme activity in individuals with at least one T allele, or whether those individuals have a higher folate requirement than the RDA (25).

Disease Prevention

Adverse pregnancy outcomes

Neural tube defects

Fetal growth and development are characterized by widespread cell division. Adequate folate is critical for DNA and RNA synthesis. Neural tube defects (NTDs) arise from failure of embryonic neural tube closure between the 21st and 27th days after conception, a time when many women may not even realize they are pregnant (26). NTDs include various malformations, such as lesions of the brain (e.g., anencephaly, encephalocele) or lesions of the spine (spina bifida), which are devastating and life-threatening (27). The prevalence of NTDs in the United States prior to fortification of food with folic acid was estimated to be 1 per 1,000 pregnancies (1). Results of randomized trials have demonstrated 60% to 100% reductions in NTD cases when women consumed folic acid supplements in addition to a varied diet during the periconceptional period (about one month before and at least one month after conception) (28, 29). The results of these and other studies prompted the US Public Health Service to recommend that all women capable of becoming pregnant consume 400 μg of folic acid daily to prevent NTDs. Women with a previously affected pregnancy were also advised to receive 4,000 μg (4 mg) of folic acid daily in order to reduce NTD recurrence (30). These recommendations were made to all women of childbearing age because adequate folate must be available very early in pregnancy, and because many pregnancies in the US are unplanned (31).

Despite the effectiveness of folic acid supplementation in improving folate status, it appears that globally only 30% of women who become pregnant correctly follow the recommendation, and there is some concern that young women from minority ethnic groups and lower socioeconomic backgrounds are the least likely to follow the recommendation (32-34). To decrease the incidence of NTDs, the US FDA implemented legislation in 1998 requiring the fortification of all enriched grain products with 1.4 mg of folic acid per kg of grain (see Sources). The required level of folic acid fortification in the US was initially estimated to provide 100 μg of additional folic acid in the average person's diet, though it probably provides even more due to overuse of folic acid by food manufacturers (25, 35). The National Birth Defects Prevention Network reported about a 30% decrease in the prevalence of NTDs in the US compared to the pre-fortification period, and the post-fortification prevalence of NTDs is 0.69 cases per 1,000 live births and fetal deaths (36).

Also, a genetic component in NTD etiology is evidenced by the increased risk in women with a family history of an NTD and also by variations in risk among ethnicities (37). Moreover, NTD occurrence can be attributed to specific folate-gene interactions. The *MTHFR* c.677C>T polymorphism and other genetic variations can increase the folate requirement and susceptibility for an NTD-affected pregnancy. Prior to the fortification era, a case-control study showed that both red blood cell and serum folate concentrations were significantly lower in pregnant women with the T/T and C/T variants compared to the wild-type C/C genotype (22), suggesting inadequate folate metabolism with specific maternal genotypes. A meta-analysis of 25 case-control studies, including 2,429 case mothers and 3,570 control mothers, showed a positive association between the maternal *MTHFR* c.677C>T polymorphism and NTDs (38). Another *MTHFR* variant, an A-to-C change at position 1298, has also been associated with reduced MTHFR activity and increased NTD risk (39). Individuals heterozygous for both of these *MTHFR* variants (677C/T + 1298A/C) exhibit lower plasma folate and higher homocysteine concentrations than individuals with 677C/T + 1298A/A (40). Combined genotypes with homozygosity G/G for the reduced folate carrier transporter (*RFC-1*) polymorphism (c.80A>G) could further contribute to NTD occurrence (41). The degree of NTD risk was also assessed with additional *MTHFR* polymorphisms (c.116C>T, c.1793G>A) (42), as well as with mutations affecting other enzymes of the one-carbon metabolism, including methionine synthase (*MTR* c.2756A>G) (43), methionine synthase reductase (*MTRR* c.66A>G) (44), and methylenetetrahydrofolate dehydrogenase (*MTHFD1* c.1958G>A) (45). While maternal genotype can impact pregnancy outcome, it appears that gene-gene interactions between mother and fetus influence it further. The risk of NTD was increased by certain genetic combinations, including maternal (*MTHFR* c.677C>T)-fetal (*MTHFR* c.677C>T) and maternal (*MTRR* c.66A>G)-fetal (*MTHFR* c.677C>T) interactions (43, 44, 46). Finally, vitamin B_{12} status has been associated with NTD risk modification in the presence of specific polymorphisms in one-carbon metabolism (47).

Cardiovascular malformations

Congenital anomalies of the heart are a major cause of infant mortality but also cause deaths in adulthood (48). Using data from the European Registration of Congenital Anomalies and Twins (EUROCAT) database, a case-control study, involving 596 cases and 2,359 controls, found that consumption of at least 400 μg/day of folic acid during the periconceptual period (one month before conception through eight weeks' post-conception, covering the period of embryonic heart development) was associated with an 18% reduced risk of congenital heart defects (49). Recent meta-analyses of 20 to 25 case-control and family-based studies observed positive associations between maternal, fetal, or paternal *MTHFR* c.677C>T variant and incidence of congenital heart defects (50, 51). Additional studies are needed to elucidate the effects of gene-nutrient interactions on the risk of congenital heart defects; however, the currently available research indicates that adequate folate intake may play an important role.

Orofacial clefts

Maternal folate status during pregnancy may influence the risk of congenital anomalies called orofacial clefts, namely cleft lip with or without cleft palate (CL/P) (52). A population-based case-control study in Norway investigated the impact of folic acid supplements in mothers of 377 newborns with CL/P, 196 with cleft palate only (CPO) and 763 controls (53). Although dietary intakes or supplements (during the first three months of pregnancy) on their own did not significantly modify the risk of CL/P, the study reported a 64% lower risk among women taking multivitamin and folic acid (≥400 μg daily) supplements in addition to dietary folates. In the same population, polymorphisms in the cystathionine β-synthase (*CBS*) gene (c.699C>T) or *MTHFR* gene (c.677C>T; when folate intake was below 400 μg/day) appeared protective, while other gene variants in the folate/one-carbon metabolism could not be linked to CL/P (54, 55). However, a recent meta-analysis of 18 studies showed an elevation of CL/P risk with the maternal 677T/T homozygosity (56). Additional studies are needed to evaluate the risk of CL/P while integrating both genetic polymorphism and folate intake parameters. Epidemiological evidence supporting a role for folate in the risk of CPO is lacking.

Other adverse pregnancy outcomes

Low birth weight has been associated with increased risk of mortality during the first year of life and may also influence health outcomes during adulthood (57). A recent systematic review and meta-analysis of eight randomized controlled trials found a positive association between folic acid supplementation and birth weight; no association with length of gestation was observed (58). Additionally, a prospective cohort study of 306 pregnant adolescents associated low folate intakes and maternal folate status during the third trimester of pregnancy with higher incidence of small for gestational age births (birth weight <10th percentile) (59). Moreover, the maternal c.677C>T *MTHFR* genotype and increased homocysteine concentrations, considered an indicator of functional folate deficiency, have been linked to lower birth weights (60).

Elevated blood homocysteine concentrations have also been associated with increased incidence of miscarriage and other pregnancy complications, including preeclampsia and placental abruption (61). A large retrospective study showed that plasma homocysteine in Norwegian women was strongly related to adverse outcomes and complications, including preeclampsia, premature delivery, and very low birth weight, in previous pregnancies (62). A recent meta-analysis of 51 prospective cohort studies linked the c.677C>T *MTHFR* variant with increased risk of preeclampsia in Caucasian and East Asian populations, reinforcing the notion that folate metabolism may play a role in the condition (63). A large multicenter, randomized, controlled trial, the Folic Acid Clinical Trial (FACT), has been initiated to evaluate whether the daily supplementation of up to 5.1 mg of folic acid throughout pregnancy could prevent preeclampsia and other adverse outcomes (e.g., maternal death, placental abruption, preterm delivery) in high-risk women (64). Adequate folate intake during pregnancy protects against megaloblastic anemia (65). A recent case-control study found a reduction in risk of autism spectrum disorders with daily folic acid consumption of 600 μg or more before and during pregnancy when mother and child carried the c.677C>T *MTHFR* genotype (66).

Thus, it is reasonable to maintain folic acid supplementation throughout pregnancy, even after closure of the neural tube, in order to decrease the risk of other problems during pregnancy. Moreover, recent systematic reviews of observational studies found no evidence of an association between folate exposure during pregnancy and adverse health outcomes in offspring, in particular childhood asthma and allergies (67, 68).

Cardiovascular disease

Homocysteine and cardiovascular disease

The results of more than 80 studies indicate that even moderately elevated concentrations of homocysteine in the blood increase the risk of cardiovascular disease (CVD) (4). Possible predispositions to vascular accidents have also been linked to genetic deficiencies in homocysteine metabolism in certain populations (69). The mechanism by which homocysteine may increase the risk of vascular disease has been the subject of a great deal of research, but it may involve adverse effects of homocysteine on blood clotting, arterial vasodilation, and thickening of arterial walls (70). Although increased homocysteine concentrations in the blood have been consistently associated with increased risk of CVD, it is unclear whether lowering circulating homocysteine will reduce CVD risk (see Folate and homocysteine). Research had initially predicted that a prolonged decrease in serum homocysteine level of 3 micromoles/liter would lower the risk of CVD by up to 25% and be a reasonable treatment goal for individuals at high risk (71, 72). However, the analysis of recent clinical trials of B-vitamin supplementation has shown that lowering homocysteine concentrations did not prevent the occurrence of a second cardiovascular event in patients with existing CVD (73, 74). Consequently, the American Heart Association recommends screening for elevated total homocysteine concentrations only in "high risk" individuals, for example, in those with personal or family history of premature cardiovascular disease, malnutrition or malabsorption syndromes, hypothyroidism, kidney failure, lupus, or individuals taking certain medications (nicotinic acid, theophylline, bile acid-binding resins, methotrexate, and L-dopa).

Folate and homocysteine

Folate-rich diets have been associated with decreased risk of CVD, including coronary artery disease, myocardial infarction (heart attack), and stroke. A study that followed 1,980 Finnish men for 10 years found that those who consumed the most dietary folate had a 55% lower risk of an acute coronary event when compared to those who consumed the least dietary folate (75). Of the three B-vitamins that regulate homocysteine concentrations, folic acid has been shown to have the greatest effect in lowering basal concentrations of homocysteine in the blood when there is no coexisting deficiency of vitamin B_{12} or vitamin B_6 (see Nutrient interactions) (76). Increasing folate intake through folate-rich food or supplements has been found to reduce homocysteine concentrations (77). Besides, blood homocysteine concentrations have declined since the FDA mandated folic acid fortification of the grain supply in the US (25). A meta-analysis of 25 randomized controlled trials, including almost 3,000 subjects, found that folic acid supplementation with 800 μg/day or more could achieve a maximal 25% reduction in plasma homocysteine concentrations. In this meta-analysis, daily doses of 200 μg and 400 μg of folic acid were associated with a 13% and 20% reduction in plasma homocysteine, respectively (78). A supplement regimen of 400 μg of folic acid, 2 mg of vitamin B_6, and 6 μg of vitamin B_{12} has been advocated by the American Heart Association if an initial trial of a folate-rich diet (see Sources) is not successful in adequately lowering homocysteine concentrations (79).

Several polymorphisms in folate/one-carbon metabolism modify homocysteine concentrations in blood (80). In particular, the effect of the c.677C>T *MTHFR* variant has been examined in relation to folic acid fortification policies worldwide. The analysis of randomized trials, including 59,995 subjects without a history of CVD, revealed that the difference in homocysteine concentrations between T/T and C/C genotypes was greater in low-folate regions compared to regions with food fortification policy (3.12 vs. 0.13 micromoles/liter) (81). Although folic acid supplementation effectively decreases homocysteine concentrations, it is not yet clear whether it also decreases risk for CVD. A recent meta-analysis of 19 randomized clinical trials, including 47,921 subjects with preexisting cardiovascular or renal disease, found that homocysteine lowering through folic acid and other B-vitamin supplementation failed to reduce the incidence of CVD despite significant reductions in plasma homocysteine concentrations (74). Other meta-analyses have confirmed the lack of causality between the lowering of homocysteine and the risk of CVD (80-82), including the risk of stroke (83, 84). Consequently, the American Heart Association removed its recommendation for using folic acid to prevent cardiovascular disease in high-risk women (85). It should be noted that the majority of prevention trials to date have been performed in CVD patients with advanced disease. The evidence supporting a beneficial role for folate and related B-vitamins appears to be strongest for the primary prevention of stroke (86). The introduction of mandatory folic acid fortification has been associated with a decline in stroke-related mortality in North America, adding further support to the potential benefit of enhancing folate status and/or lowering homocysteine in the prevention of stroke (87).

Despite the controversy regarding the role of homocysteine lowering in CVD prevention, some studies have investigated the effect of folic acid supplementation on the development of atherosclerosis, a known risk factor for vascular accidents. The measurement of the carotid intima-media thickness (CIMT) is a surrogate endpoint for early atherosclerosis and a predictor for cardiovascular events (88). The meta-analysis of 10 randomized trials testing the effect of folic acid supplementation showed a significant reduction in CIMT in subjects with chronic kidney diseases and in those at high risk for CVD, but not in healthy participants (89). Endothelial dysfunction is a common feature in atherosclerosis and vascular disease. High doses of folic acid (400-10,000 μg/day) have been associated with improvements in vascular health in both healthy and CVD subjects (90). Although recent trials failed to demonstrate any cardiovascular protection from folic acid supplementation, low folate intake is a known risk factor for vascular disease, and more research is needed to explore the role of folate in maintaining vascular health (91).

Cancer

Cancer is thought to arise from DNA damage in excess of ongoing DNA repair and/or the inappropriate expression of critical genes. Because of the important roles played by folate in DNA and RNA synthesis and methylation, it is possible that inadequate folate intake contributes to genome instability and chromosome breakage that often characterize cancer development. In particular, DNA replication and repair are critical for genome maintenance, and the shortage in nucleotides caused by folate deficiency might lead to genome instability and DNA mutations. A decrease in 5,10-methylene THF can compromise the conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP) by the enzyme thymidylate synthase (TS), causing uracil accumulation and thymine depletion. This could then lead to uracil misincorporation into DNA during replication or repair, and cause DNA damage, including point mutations and strand breaks (92). Since 5,10-methylene THF is also the MTHFR enzyme substrate, it is plausible that a reduction of MTHFR activity with the c.677C>T polymorphism may increase the use of 5,10-methylene THF for thymidylate synthesis and prevent DNA damage. However, this hypothesis might only be valid in a situation of folate deficiency (93). Conversely, it was argued that folic acid supplementation could fuel DNA synthesis, therefore promoting tumor growth. This is supported by the observation that TS can function like a tumor promoter (oncogene), while a reduction in TS activity is linked to a lower risk of cancer (94, 95). Additionally, antifolate molecules that block the thymidylate synthesis pathway are successfully used in cancer therapy (96). Folate also controls the homocysteine/methionine cycle and the pool of S-adenosylmethionine (SAM), the methyl donor for methylation reactions. Thus, folate deficiency may impair DNA and protein methylation and alter the expression of genes involved in DNA repair, proliferation and cell death. Global DNA hypomethylation, a typical hallmark of cancer, causes genome instability and chromosome breaks (reviewed in 97).

The consumption of at least five servings of fruit and vegetables daily has been consistently associated with a decreased incidence of cancer (98). Fruit and vegetables are excellent sources of folate, which may play a role in their anti-carcinogenic effect. Observational studies have found diminished folate status to be associated with site-specific cancers. While food fortification is mandatory in the US (since 1998; see Sources), concerns about the impact of high folic acid intakes on health have delayed the practice in several other countries (99). However, the most recent meta-analyses of folic acid intervention trials (supplemental doses ranging from 500 to 5,000 μg/day for at least one year) did not show any specific benefit or harm regarding total and site-specific cancer incidence (100, 101).

Colorectal cancer

A pooled analysis of 13 prospective cohort studies, which followed a total of 725,134 individuals for a 7 to 20-year period, revealed a modest, inverse association between dietary and total (from food and supplements) folate intake and colon cancer risk. Specifically, a 2% decrease in colon cancer risk was estimated for every 100 μg/day increase in total folate intake (102). A large US prospective study, which followed 525,488 subjects, ages 50 to 71 years between 1995 and 2006, correlated dietary folate, supplemental folic acid, and total folate intakes with a decreased colorectal cancer (CRC) risk (103). However, when stratified by gender, there was no association between dietary folate intake and CRC risk in women (103, 104). A lack of association between CRC risk and dietary, supplemental, and total folate intakes was also reported in another prospective study that followed more than 90,000 US postmenopausal women during an 11-year period encompassing pre- and post-fortification periods (105). These data suggest the possible influence of gender over CRC risk modification by folate. In the latter study, a significant but transient risk elevation was also observed during the post-fortification era; however, some have asserted that this is unlikely to be caused by increased folate intake due to mandatory fortification (106). Finally, a meta-analysis of 18 case-control studies found a slight reduction in CRC risk with folate from food (107). However, it is important to note that the case-control studies were highly heterogeneous, and that the authors stated that dietary fiber, vitamins, and alcohol intake could have confounded their results. Moreover, the lower limit of the highest quantile of folate intake was highly variable, ranging from 270 to 1,367 μg/day (107).

While most epidemiological research shows a protective effect of folate against colorectal cancer development, it has been suggested that high doses of supplemental folic acid may actually accelerate tumor growth in cancer patients (108). Whereas higher folate status within the normal dietary range is widely considered to be protective against cancer, some investigators remain concerned that exposure to excessively high folic acid intakes may increase the growth of pre-existing neoplasms (108). Several clinical trials addressed the effect of folic acid supplementation in patients with a history of colorectal adenoma, with trials finding a risk reduction or no effect of supplemental folic acid (109-112). A recent meta-analysis of three large randomized controlled trials in high-risk subjects did not demonstrate any increase in colorectal adenoma recurrence in subjects supplemented with 500 or 1,000 μg/day of folic acid for 24 to 42 months when compared with placebo treatment (113).

As suggested earlier, the *MTHFR* 677T/T genotype might prevent uracil misincorporation and protect DNA integrity and stability under low-folate conditions. A meta-analysis of 62 case-control and two cohort studies revealed that while the T/T variant reduces CRC risk by 12% compared to both C/T and C/C genotypes, the risk was decreased by 30% with high (348-1,583 μg/day) versus low total folate intakes (264-450 μg/day), irrespective of the genotype (114). A common polymorphism (c.2756A>G) in the *MTR* gene, which codes for methionine synthase, was also examined in relation with the risk of colorectal adenoma and cancer. Methionine synthase catalyzes the simultaneous conversion of homocysteine and 5-methylene THF into methionine and TFH, respectively. The recent meta-analysis of 27 case-control studies showed no association between *MTR* variant and cancer risk (115).

Although alcohol consumption interferes with the absorption and metabolism of folate (16), one case-control and five prospective cohort studies have reported either reduction in CRC risk among nondrinkers compared to drinkers or a lack of association (107). However, in a large prospective study that followed more than 28,000 male health professionals for 22 years, intake of more than two alcoholic drinks (>30 grams of alcohol) per day augmented CRC risk by 42% during the pre-fortification period. CRC risk was not increased during the post-fortification period, suggesting that it is the combination of high alcohol and low folate intake that might increase CRC risk. Yet, another prospective study that followed more than 69,000 female nurses for 28 years did not report a significant increase in CRC risk with alcohol intake before and after the mandatory folic acid fortification (116). In some studies, individuals who are homozygous for the c.677C>T *MTHFR* polymorphism (T/T) have been found to be at decreased risk for colon cancer when folate intake is adequate. However, when folate intake is low and/or alcohol intake is high, individuals with the (T/T) genotype have been found to be at increased risk of colorectal cancer (117, 118).

Breast cancer

Several prospective cohort and case-control studies investigating whether folate intake affects breast cancer risk have reported mixed results (119). A meta-analysis of 15 prospective studies and one nested case-control study found no relationship with dietary folate intake (120). Moderate alcohol intake has been associated with increased risk of breast cancer in women (121). The results of three prospective studies suggested that increased folate intake may reduce the risk of breast cancer in women who regularly consume alcohol (122-124). Thus, high folate intake might be associated with a risk reduction only in women whose breast cancer risk is raised by alcohol consumption. A very large prospective study in more than 88,000 nurses reported that folic acid intake was not associated with breast cancer in women who consumed less than one alcoholic drink per day. However, in women consuming at least one alcoholic drink per day, folic acid intake of at least 600 μg daily resulted in about half the risk of breast cancer compared with women who consumed less than 300 μg of folic acid daily (124). Nevertheless, whether and how alcohol consumption increases breast cancer risk is still subject to discussion (125, 126). Finally, recent meta-analyses evaluating the influence of polymorphisms in one-carbon metabolism on cancer risk found that specific variants in the gene encoding thymidylate synthase increased the risk of breast cancer in certain ethnic populations (127, 128).

Childhood cancers

The incidence of Wilms' tumors (kidney cancer) and certain types of brain cancers (neuroblastoma, ganglioneuroblastoma, and ependymoma) in children has decreased since the mandatory fortification of the US grain supply in 1998 (129). However, incidence rates were unchanged between the pre- and post-fortification periods for leukemia—a predominant childhood malignancy. Despite earlier studies linking maternal folic acid supplementation during pregnancy with the reduced risk of childhood leukemia, more recent investigations have found little evidence to support a preventive effect of folic acid (130). Several meta-analyses have also found little to no protective effect with *MTHFR* polymorphisms; however, the most recent meta-analysis of 22 case-control studies found a reduction in the risk of acute lymphoblastic leukemia (ALL) with the c.677C>T variant in Caucasians and Asians (131).

Alzheimer's disease and cognitive impairment

Alzheimer's disease (AD) is the most common form of dementia, affecting more than 5 million individuals over 65 years old in the US (132). β-amyloid plaque deposition, Tau protein-forming tangles, and increased cell death in the brain of AD patients have been associated with cognitive decline and memory loss. One study associated increased consumption of fruit and vegetables, which are abundant sources of folate, with a reduced risk of developing dementia and AD in women (133). Through its role in nucleic acid synthesis and methyl donor provision for methylation reactions, folate is critical for normal brain development and function, not only during pregnancy and after birth, but also later in life (134). In one cross-sectional study of elderly women, AD patients had significantly higher homocysteine and lower red blood cell folate concentrations compared to healthy individuals. However, there was no difference in the level of serum folate between groups, suggesting that long-term folate status, rather than recent folate intake, may be associated with the risk of AD (135).

Several investigators have described associations between increased homocysteine concentrations and cognitive impairment in the elderly (136), but prospective cohort studies have not found higher folate intakes to be associated with improved cognition (137, 138). Higher homocysteine concentrations were found in individuals suffering from dementia, including AD and vascular dementia, compared to healthy subjects (139, 140). Although deficiencies in folate, vitamin B_{12}, and vitamin B_6 could increase homocysteine concentrations, a reduction in vitamin concentrations in the serum of AD patients compared to healthy individuals could not be attributed to decreased vitamin intakes (141). It is not presently clear whether serum homocysteine is a risk factor for developing dementia or simply associated with the cognitive decline. In the last decade, a number of clinical trials have tested the use of B-vitamins to lower homocysteine and prevent or delay cognitive decline. A meta-analysis of nine randomized, placebo-controlled trials of folic acid supplementation (0.2 to 15 mg/day for a median duration of six months) in healthy individuals over 45 years of age failed to find a short-term effect on cognitive functions, including memory, speed, language, and executive functions (142). More recently, a meta-analysis of 19 randomized, placebo-controlled trials of B-vitamin supplementation found no difference in cognitive parameters between the treatment and placebo groups, despite the treatment effectively lowering homocysteine concentrations (143). Inconsistent findings across trials may be due to differences in design and methodology (reviewed in 144).

Nevertheless, a two-year randomized, placebo-controlled trial in 168 elderly subjects with mild cognitive impairment recently described the benefits of a daily regimen of 800 μg of folic acid, 500 μg of vitamin B_{12}, and 20 mg of vitamin B_6 (145, 146). Atrophy of specific brain regions affected by AD was observed in individuals of both groups, and this atrophy correlated with cognitive decline; however, the B-vitamin treatment group experienced a smaller loss of gray matter compared to the placebo group (0.5% vs. 3.7%). A greater benefit was seen in subjects with higher baseline homocysteine concentrations, suggesting the importance of lowering circulating homocysteine in prevention of cognitive decline and dementia. Although encouraging, the effect of B-vitamin supplementation needs to be further studied in larger trials that evaluate long-term outcomes, such as the incidence of AD.

Disease Treatment

Metabolic diseases

Folinic acid (see **Figure 1** above), a tetrahydrofolic acid derivative, is used in the clinical management of rare inborn errors that affect folate transport or metabolism (reviewed in 147). Such conditions are of autosomal recessive inheritance, meaning only individuals receiving two copies of the mutated gene (one from each parent) develop the disease.

Hereditary folate malabsorption

Hereditary folate malabsorption is caused by mutations in the *SLC46A1* gene coding for the folate transporter PCFT and typically affects gastrointestinal folate absorption and folate transport into the brain (148). Patients present with low to undetectable concentrations of folate in serum and cerebrospinal fluid, pancytopenia (low number of all blood cells), impaired immune responses that increase susceptibility to infections, and a general failure to thrive (149). Neurologic symptoms, including seizures, have also been observed (150). Clinical improvements have been recorded following parenteral provision of folinic acid (151).

Cerebral Folate Deficiency (CFD) syndrome

CFD is characterized by low levels of folate coenzymes in cerebrospinal fluid despite normal concentrations of folate in blood. Folate transport across the blood-brain barrier is compromised in CFD and has been linked either to the presence of antibodies blocking the folate receptor FRα or to mutations in the *FOLR1* gene encoding FRα (152, 153). Neurologic abnormalities, along with visual and hearing impairments, have been described in children with CFD; autism spectrum disorder (ASD) is present in some cases. Folinic acid (also known as leucovorin) can enter the brain and normalize the level of folate coenzymes and has been shown to normalize folate concentrations and improve various social interactions in CFD, including mood, behavior, and verbal communication in children with ASD (152, 154, 155).

Dihydrofolate reductase (DHFR) deficiency

DHFR is the NADPH-dependent enzyme that catalyzes the reduction of dihydrofolic acid (DHF) to tetrahydrofolic acid (THF). DHFR is also required to convert folic acid to DHF. DHFR deficiency is characterized by megaloblastic anemia and cerebral folate deficiency causing intractable seizures and mental deficits. Although folinic acid treatment can alleviate the symptoms of DHFR deficiency, early diagnosis is essential to prevent irreversible brain damage and improve clinical outcomes (156, 157).

Sources

Food sources

Green leafy vegetables (foliage) are rich sources of folate and provide the basis for its name. Citrus fruit juices, legumes, and fortified foods are also excellent sources of folate (1); the folate content of fortified cereal varies greatly. A number of folate-rich foods are listed in **Table 2**, along with their folate content in micrograms (μg). For more information on the nutrient content of specific foods, search USDA's FoodData Central.

Table 2. Some Food Sources of Folate and Folic Acid

Food	Serving	Folate (μg DFEs)
Lentils (mature seeds, cooked, boiled)	½ cup	179
Garbanzo beans (chickpeas, cooked, boiled)	½ cup	141
Asparagus (cooked, boiled)	½ cup (~6 spears)	134
Spinach (cooked, boiled)	½ cup	131
Lima beans (large, mature seeds, cooked, boiled)	½ cup	78
Orange juice (raw)	6 fl. oz.	56
Spaghetti (enriched, cooked)	1 cup	167*
White rice (enriched, cooked)	1 cup	153*
Bread (enriched)	1 slice	84*

*To help prevent neural tube defects, the US FDA required the addition of 1.4 milligrams (mg) of folic acid per kilogram (kg) of grain to be added to refined grain products, which are already enriched with niacin, thiamin, riboflavin, and iron, as of January 1, 1998. The addition of nutrients to food in order to prevent a nutritional deficiency or restore nutrients lost in processing is known as fortification. The FDA initially estimated that this level of fortification would increase dietary intake by an average of 100 µg folic acid/day (26). However, further evaluations based on observational studies suggested increases twice that predicted by the FDA (35). The prevalence of low folate concentrations in both serum and red blood cells is currently below 1% in the US population, compared to 24% and 3.5%, respectively, before the fortification period (158).

Supplements

The principal form of supplementary folate is folic acid. It is available in single-ingredient and combination products, such as B-complex vitamins and multivitamins. Doses of 1 mg or greater require a prescription (159). Additionally, folinic acid, a tetrahydrofolic acid derivative, is used to manage certain metabolic diseases (see Disease Treatment). Further, the US FDA has approved the supplementation of folate in oral contraceptives. The addition of levomefolate calcium (the calcium salt of MeTHF; 451 µg/tablet) to oral contraceptives is intended to raise folate status in women of childbearing age (160). According to a US national survey, only 24% of non-pregnant women aged 15-44 years are meeting the current recommendation of 400 µg/day of folic acid (161).

Safety

Toxicity

No adverse effects have been associated with the consumption of excess folate from food. Concerns regarding safety are limited to synthetic folic acid intake. Deficiency of vitamin B_{12}, though often undiagnosed, may affect a significant number of people, especially older adults (see the article on Vitamin B_{12}). One symptom of vitamin B_{12} deficiency is megaloblastic anemia, which is indistinguishable from that associated with folate deficiency (see Deficiency). Large doses of folic acid given to an individual with an undiagnosed vitamin B_{12} deficiency could correct megaloblastic anemia without correcting the underlying vitamin B_{12} deficiency, leaving the individual at risk of developing irreversible neurologic damage. Such cases of neurologic progression in vitamin B_{12} deficiency have been mostly seen at folic acid doses of 5,000 µg (5 mg) and above. In order to be very sure of preventing irreversible neurological damage in vitamin B_{12}-deficient individuals, the Food and Nutrition Board of the US Institute of Medicine advises that all adults limit their intake of folic acid (supplements and fortification) to 1,000 µg (1 mg) daily (**Table 3**). The Board also noted that vitamin B_{12} deficiency is very rare in women in their childbearing years, making the consumption of folic acid at or above 1,000 µg/day unlikely to cause problems (1); however, there are limited data on the effects of large doses.

Table 3. Tolerable Upper Intake Level (UL) for Folic Acid

Age Group	UL (µg/day)
Infants 0-12 months	Not possible to establish*
Children 1-3 years	300
Children 4-8 years	400
Children 9-13 years	600
Adolescents 14-18 years	800
Adults 19 years and older	1,000
*Source of intake should be from food and formula only.	

The saturation of DHFR metabolic capacity by oral doses of folic acid has been associated with the appearance of unmetabolized folic acid in blood (162). Hematologic abnormalities and poorer cognition have been associated with the presence of unmetabolized folic acid in vitamin B_{12}-deficient older adults (≥60 years) (163, 164). A small study conducted in postmenopausal women also raised concerns about the effect of exposure to unmetabolized folic acid on immune function (165). In a small, randomized, open-label trial in 38 women of reproductive age receiving 30 weeks of daily multivitamin supplements, daily supplementation with either 1.1 mg or 5 mg of folic acid resulted in the transient appearance of unmetabolized folic acid in blood over the first 12 weeks of supplementation (166). However, unmetabolized folic acid concentrations returned to baseline levels at the end of the study, suggesting that adaptive mechanisms eventually converted folic acid to reduced forms of folate. Nonetheless, the use of supplemental levomefolate (5-methyl THF) may provide an alternative to prevent the potential negative effects of unconverted folic acid in older adults.

Drug interactions

When nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin or ibuprofen, are taken in very large therapeutic dosages (i.e., to treat severe arthritis), they may interfere with folate metabolism. In contrast, routine use of NSAIDs has not been found to adversely affect folate status. The anticonvulsant, phenytoin, has been shown to inhibit the intestinal absorption of folate, and several studies have associated decreased folate status with long-term use of the anticonvulsants, phenytoin, phenobarbital, and primidone (167). However, few studies controlled for differences in dietary folate intake between anticonvulsant users and nonusers. Also, taking folic acid at the same time as the cholesterol-lowering agents, cholestyramine and colestipol, may decrease the absorption of folic acid (159). Methotrexate is a folate antagonist used to treat a number of diseases, including cancer, rheumatoid arthritis, and psoriasis. Some of the side effects of methotrexate are similar to those of severe folate deficiency, and supplementation with folic or folinic acid is used to reduce antifolate toxicity. Other antifolate molecules currently used in cancer therapy include aminopterin, pemetrexed, pralatrexate, and raltitrexed (96). Further, a number of other medications have been shown to have antifolate activity, including trimethoprim (an antibiotic), pyrimethamine (an antimalarial), triamterene (a blood pressure medication), and sulfasalazine (a treatment for ulcerative colitis). Early studies of oral contraceptives (birth control pills) containing high doses of estrogen indicated adverse effects on folate status; however, this finding has not been supported in more recent studies that used low-dose oral contraceptives and controlled for dietary folate (168).

Linus Pauling Institute Recommendation

The available scientific evidence shows that adequate folate intake prevents neural tube defects and other poor outcomes of pregnancy; is helpful in lowering the risk of some forms of cancer, especially in genetically susceptible individuals; and may lower the risk of cardiovascular disease. The Linus Pauling Institute recommends that adults take a daily multivitamin/mineral supplement, which typically contains 400 µg of folic acid, the Daily Value (DV). Even with a larger than average intake of folic acid from fortified food, it is unlikely that an individual's daily folic acid intake would regularly exceed the tolerable upper intake level of 1,000 µg/day established by the Institute of Medicine (see Safety).

Older adults (>50 years)

The recommendation for 400 µg/day of supplemental folic acid as part of a daily multivitamin/mineral supplement, in addition to a folate-rich diet, is especially important for older adults because blood homocysteine concentrations tend to increase with age (see Disease Prevention).

Summary

- Dietary precursors of nicotinamide adenine dinucleotide (NAD), including nicotinic acid, nicotinamide, and nicotinamide riboside, are collectively referred to as niacin or vitamin B_3. The essential amino acid tryptophan can also be converted into NAD via the kynurenine pathway. *(More information)*
- NAD can be phosphorylated (NADP) and reduced (NADH and NADPH). NAD functions in oxidation-reduction (redox) reactions and non-redox reactions. *(More information)*
- Pellagra is the disease of severe niacin deficiency. It is characterized by symptoms affecting the skin, the digestive system, and the nervous system; pellagra can lead to death if left untreated. *(More information)*
- Causes of niacin deficiency include inadequate oral intake, poor bioavailability from unlimed grains, defective tryptophan absorption, metabolic disorders, and the long-term use of chemotherapeutic treatments. *(More information)*
- Dietary intake requirements for niacin are based on the urinary excretion of niacin metabolites. *(More information)*
- NAD is the sole substrate for PARP enzymes and sirtuins involved in DNA repair activities; thus, NAD is critical for genome stability. Several studies, mostly using *in vitro* and animal models, suggest a possible role for niacin in cancer prevention. In a recent phase III trial, a daily pharmacologic dose of nicotinamide was found to reduce the rate of premalignant skin lesions and nonmelanoma cancers in high-risk subjects. *(More information)*
- Despite promising initial results, nicotinamide administration has failed to prevent or delay the onset of type 1 diabetes mellitus in high-risk relatives of type 1 diabetic patients. Future research might explore the use of nicotinamide in combined therapy and evaluate activators of NAD-dependent enzymes. *(More information)*
- At pharmacologic doses, nicotinic acid improved lipid profiles of patients with a history of vascular disease yet failed to reduce recurrent cardiovascular events or mortality. *(More information)*
- Elevated tryptophan breakdown in the kynurenine pathway and niacin deficiency have been reported in HIV-positive people. However, at present, a better understanding of the role of kynurenine pathway and other NAD biosynthetic pathways during HIV infection is needed to establish whether this population could benefit from niacin supplementation. *(More information)*
- Most adverse effects of niacin (nicotinic acid and nicotinamide) have been reported with pharmacological doses of nicotinic acid. The tolerable upper intake level (UL) for niacin is based on preventing skin flushing, nicotinic acid's most prominent side effect. The co-administration of laropiprant — a prostaglandin D2 receptor-1 antagonist — helps reduce nicotinic acid-induced skin flushing. *(More information)*

Niacin or vitamin B_3 is a water-soluble vitamin used by the body to form the nicotinamide coenzyme, NAD$^+$. The term 'niacin' is often used to refer to nicotinic acid (pyridine-3-carboxylic acid) only, although other vitamers with a pyridine ring, including nicotinamide (pyridine-3-carboxamide) and nicotinamide riboside, also contribute to NAD$^+$ formation (1). None of the vitamers are related to the nicotine found in tobacco, although their names are similar. Likewise, nicotine — but not nicotinic acid — is an agonist of the nicotinic receptors that respond to the neurotransmitter, acetylcholine.

Metabolism

Essential to all forms of life, the nicotinamide coenzyme NAD$^+$ is synthesized in the body from four precursors that are provided in the diet: nicotinic acid, nicotinamide, nicotinamide riboside, and tryptophan (**Figure 1**).

Figure 2 illustrates the separate biosynthetic pathways that lead to NAD$^+$ production from the various dietary precursors. NAD$^+$ is synthesized from nicotinamide and nicotinamide riboside via two enzymatic reactions, while the pathway that yields NAD$^+$ from nicotinic acid - known as the Preiss-Handler pathway — includes three steps. The kynurenine pathway is the longest NAD$^+$ biosynthetic pathway: the catabolism of tryptophan through kynurenine produces quinolinic acid, which is then converted to nicotinic acid mononucleotide, an intermediate in NAD$^+$metabolism. NAD$^+$ is then synthesized from nicotinic acid mononucleotide in the Preiss-Handler pathway (2).

All pathways generate intermediary mononucleotides — either nicotinic acid mononucleotide or nicotinamide mononucleotide. Specific enzymes, known as phosphoribosyltransferases, catalyze the addition of a phosphoribose moiety onto nicotinic acid or quinolinic acid to produce nicotinic acid mononucleotide or onto nicotinamide to generate nicotinamide mononucleotide. Nicotinamide mononucleotide is also generated by the phosphorylation of nicotinamide riboside, catalyzed by nicotinamide riboside kinases (NRKs). Further, adenylyltransferases catalyze the adenylation of these mononucleotides to form either nicotinic acid adenine dinucleotide or NAD$^+$. Nicotinic acid adenine dinucleotide is then converted to NAD$^+$ by glutamine-dependent NAD$^+$ synthetase (NADSYN), which uses glutamine as an amide group donor (**Figure 2**) (2). Of note, nicotinic acid adenine dinucleotide has been reported to form following the administration of high-dose nicotinamide riboside, suggesting that a potential deamidation could occur to convert NAD$^+$ to nicotinic acid adenine dinucleotide when the pool of NAD$^+$ is high (1).

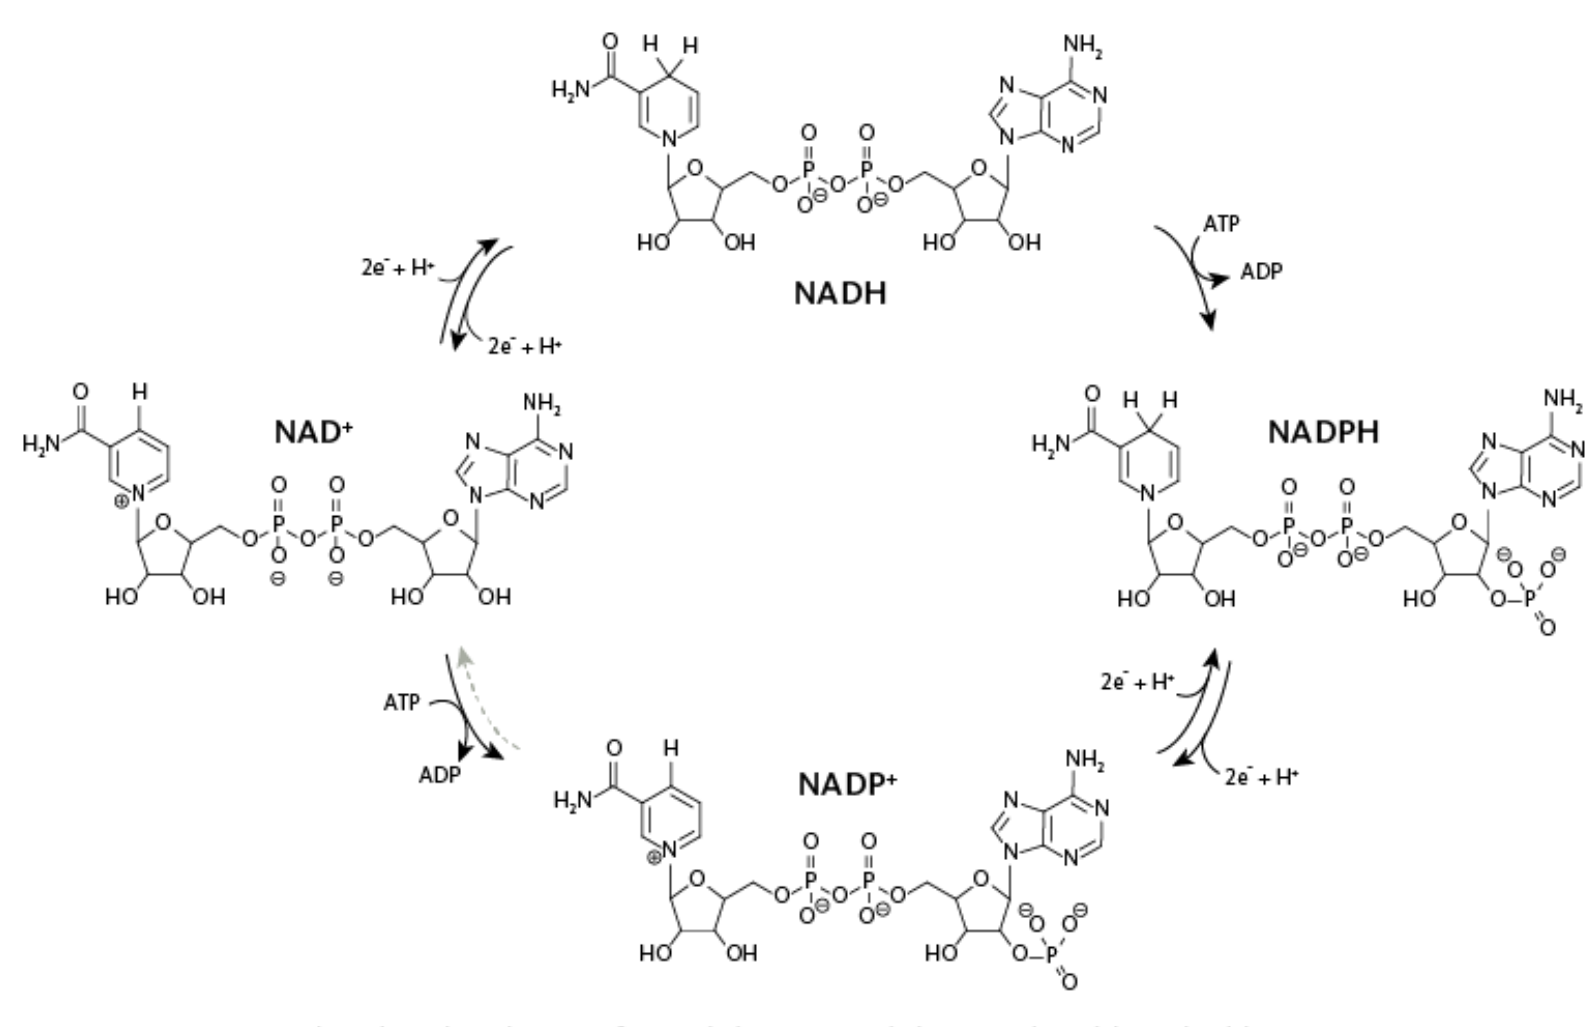
Tryptophan can be converted to quinolinic acid in the kynurenine pathway; QPRT catalyzes the conversion of quinolinic acid to nicotinic acid mononucleotide. Nicotinic acid mononucleotide is also the product of the reaction of phosphoribosylation of nicotinic acid catalyzed by NAPRT. Nicotinic acid mononucleotide is then converted to nicotinic acid adenine dinucleotide in a reaction catalyzed by NMNATs; NADSYN catalyzes the amidation of nicotinic acid adenine dinucleotide into NAD$^+$. Both nicotinamide and nicotinamide riboside are precursors of nicotinamide mononucleotide. The adenylation of nicotinamide mononucleotide catalyzed by NMNATs produces NAD$^+$. *NADSYN, Nicotinamide adenine dinucleotide synthase; NAMPT, Nicotinamide phosphoribosyltransferase; NAPRT, Nicotinic acid phosphoribosyltransferase; NMNATs, Nicotinamide mononucleotide adenylyltransferase; NRKs, Nicotinamide riboside kinases; QPRT, Quinolinate phosphoribosyltransferase.*

[Figure 2 - Click to Enlarge]

NAD kinase catalyzes the phosphorylation of NAD into NADP using adenosyl triphosphate (ATP) as the phosphoryl donor (3). The oxidation-reduction (redox) properties of the dinucleotide are not affected by the phosphorylation such that the redox pairs NAD$^+$/NADH and NADP$^+$/NADPH show similar redox potentials (4). Oxidation and reduction of the C-4 position of the nicotinamide moiety of NADand its phosphorylated form are essential for electron-transfer reactions supporting vital metabolic and bioenergetic functions in all cells (see Function). Thus, NAD and NADP are recycled back and forth between oxidized (NAD$^+$ and NADP$^+$) and reduced forms (NADH and NADPH), as shown in **Figure 3**.

Figure 3. NAD(P) Oxido-reduction Balance



The phosphorylation of NAD(H) to NADP(H) is catalyzed by a highly conserved enzyme, NAD kinase. Oxidoreductases catalyze the transfer of electrons and hydrogens between molecules using NAD(P)$^+$ and NAD(P)H as electron acceptors and donors, respectively. Thus, in electron-transfer reactions, dinucleotides are recycled back and forth between their oxidized (NAD$^+$ and NADP$^+$) and reduced (NADH and NADPH) forms.

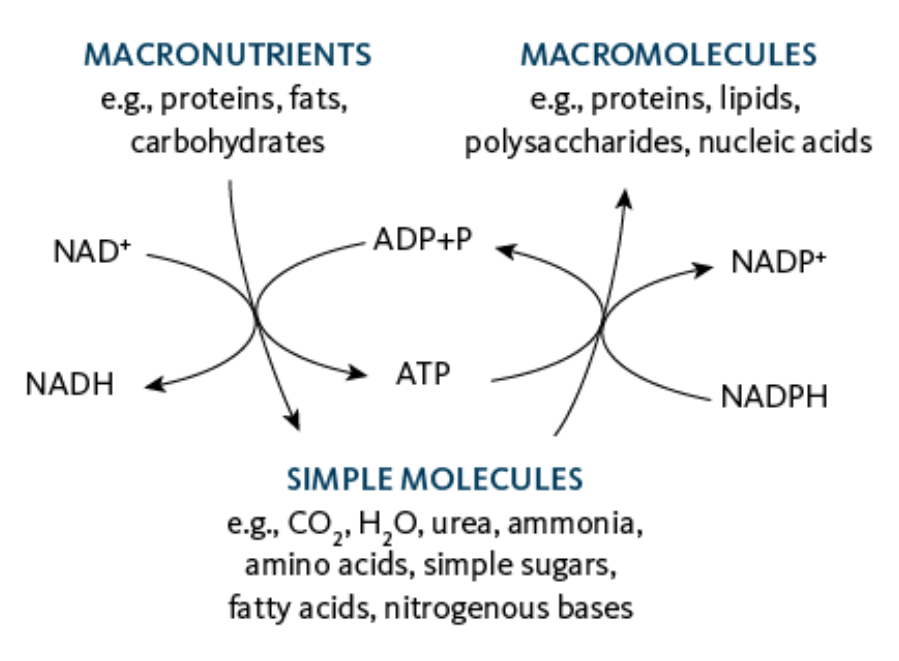
[Figure 3 - Click to Enlarge]

Function

NAD as a coenzyme in electron-transfer reactions

Living organisms derive most of their energy from redox reactions, which are processes involving the transfer of electrons. Over 400 enzymes require the niacin coenzymes, NAD and NADP, mainly to accept or donate electrons for redox reactions (5). NAD and NADP appear to support distinct functions (**Figure 4**). NAD functions most often in energy-producing reactions involving the degradation (catabolism) of carbohydrates, fats, proteins, and alcohol. NADP generally serves in biosynthetic (anabolic) reactions, such as in the synthesis of fatty acids, steroids (e.g., cholesterol, bile acids, and steroid hormones), and building blocks of other macromolecules (4). NADP is also essential for the regeneration of components of detoxification and antioxidant systems (4). To support these functions, the cell maintains NAD in a largely oxidized state (NAD$^+$) to serve as oxidizing agent for catabolic reactions, while NADP is kept largely in a reduced state (NADPH) to readily donate electrons for reductive cellular processes (4, 6).

Figure 4. Simplified Overview of NAD/NADP Function in Catabolic and Anabolic Pathways



MACRONUTRIENTS

On the left – In catabolic pathways, the oxidation of macronutrients is coupled with the reduction of NAD$^+$; NAD$^+$ accepts electrons and becomes reduced (NADH).
On the right – In anabolic pathways, the oxidation of NADPH provides electrons needed for the biosynthesis of macromolecules; NADPH donates electrons and becomes oxidized (NADP$^+$).

[Figure 4 - Click to Enlarge]

NAD as a substrate for NAD-consuming enzymes

The niacin coenzyme, NAD, is the substrate (reactant) for at least four classes of enzymes. Two classes of enzymes with mono adenosine diphosphate (ADP)-ribosyltransferase and/or poly (ADP-ribose) polymerase activities catalyze ADP-ribosyl transfer reactions. Silent information regulator-2 (Sir2)-like proteins (sirtuins) catalyze the removal of acetyl groups from acetylated proteins, utilizing ADP-ribose from NAD as an acceptor for acetyl groups. Finally, ADP-ribosylcyclases are involved in the regulation of intracellular calcium signaling.

ADP-ribosylation

Enzymes with ADP-ribosyltransferase activities were formerly divided between mono ADP-ribosyltransferases (ARTs) and poly (ADP-ribose) polymerases (PARPs). ARTs were first discovered in certain pathogenic bacteria — like those causing cholera or diphtheria — where they mediate the actions of toxins. These enzymes transfer an ADP-ribose residue moiety from NAD to a specific amino acid of a target protein, with the creation of an ADP-ribosylated protein and the release of nicotinamide.

Because most PARPs have been found to exhibit only mono ADP-ribosyltransferase activities, a new nomenclature was proposed for enzymes catalyzing ADP-ribosylation: A family of mono ADP-ribosyltransferases with homology to bacterial diphtheria toxins was named ARTD, while enzymes with either mono or poly ADP-ribosyltransferase activities and related to C2 and C3 clostridial toxins were included in the ARTC family (7, 8).

- **ARTCs** are extracellular enzymes that catalyze the mono ADP-ribosylation of membrane or secreted proteins involved in innate immunity and cell communication (2).
- **ARTDs** are intracellular enzymes with either mono or poly ADP-ribosyltransferase activities. At least 18 ARTDs have been identified. All ARTDs possess a diphtheria toxin-like catalytic domain that binds NAD$^+$. Only ARTDs 1, 2, 5, and 6 catalyze poly (ADP-ribose) transfers; the others have mono ADP-ribosyltransferase activities. ARTDs were shown to be involved in DNA repair and stress responses, cell signaling, transcription regulation, apoptosis, cell differentiation, maintenance of genomic integrity, and antiviral defense (reviewed in 8).

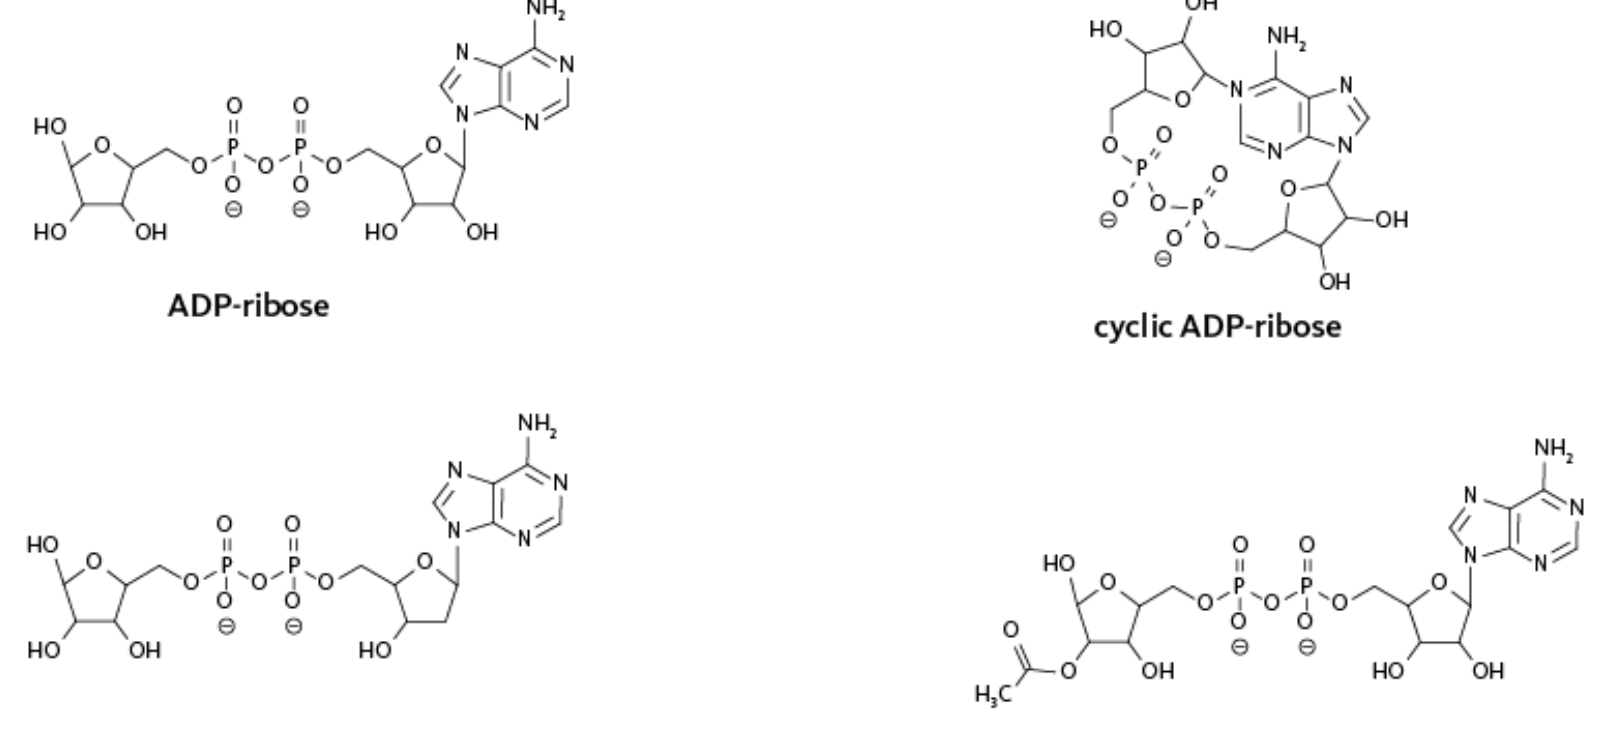
NAD-dependent deacetylation

Seven **sirtuins** (SIRT 1-7) have been identified in humans. Sirtuins are a class of NAD-dependent deacetylase enzymes that remove acetyl groups from the acetylated lysine residues of target proteins. During the deacetylation process, the acetyl group is transferred onto the ADP-ribose moiety cleaved off NAD, producing O-acetyl-ADP-ribose. Nicotinamide can exert feedback inhibition to the deacetylation reaction (9). Like ADP-ribosylation, acetylation is a post-translational modification that affects the function of target proteins. The initial interest in sirtuins followed the discovery that their activation could mimic caloric restriction, which has been shown to increase lifespan in lower organisms. Such a role in mammals is controversial, although sirtuins are energy-sensing regulators involved in signaling pathways that could play important roles in delaying the onset of age-related diseases (e.g., cardiovascular disease, cancer, dementia, arthritis). To date, the spectrum of their biological functions includes gene silencing, DNA damage repair, cell cycle regulation, and cell differentiation (10).

Calcium mobilization

In humans, CD38 and CD157 belong to a family of **NAD$^+$ glycohydrolases/ADP-ribosylcyclases**. These enzymes catalyze the formation of key regulators of calcium signaling, namely (linear) ADP-ribose, cyclic ADP-ribose, and nicotinic acid adenine dinucleotide phosphate (**Figure 5**). Cyclic ADP-ribose and nicotinic acid adenine dinucleotide phosphate works within cells to provoke the release of calcium ions from internal storage sites (i.e., endoplasmic reticulum, lysosomes, mitochondria), whereas ADP-ribose stimulates extracellular calcium entry through cell membrane TRPM2 cation channels (2). Another TRPM2 agonist, 2'-deoxy-ADP-ribose, was recently identified *in vitro*. CD38 was found to catalyze the synthesis of 2'-deoxy-ADP-ribose from nicotinamide mononucleotide and 2'-deoxy-ATP (11). *O*-acetyl-ADP-ribose generated by the activity of sirtuins also controls calcium entry through TRPM2 channels (6). Intracellular calcium-mediated signal transduction is regulated by transient calcium entry into the cell or release of calcium from intracellular stores. Calcium signaling is critically involved in processes like neurotransmission, insulin release from pancreatic β-cells, muscle cell contraction, and T-lymphocyte activation (6).

Figure 5. Calcium-mobilizing Derivatives of Niacin



[Figure 5 - Click to Enlarge]

NAD as a ligand

NAD^+ has been identified as an endogenous agonist of purinergic membrane receptors of the P2Y subclass. In particular, NAD was found to bind to P2Y1 receptor and act as an inhibitory neurotransmitter at neuromuscular junctions in visceral smooth muscles (12). Extracellular NAD^+ was also found to behave like a proinflammatory cytokine, triggering the activation of isolated granulocytes. NAD^+ binding to the P2Y11 receptor at the granulocyte surface activated a signaling cascade involving cyclic ADP-ribose and the rise of intracellular calcium, eventually stimulating superoxide generation and chemotaxis (13). Similar observations were made with lipopolysaccharide-activated monocytes (14). Extracellular $NAADP^+$ and ADP-ribose might also bind to P2Y receptors and trigger intracellular $NAADP^+$- and ADP-ribose-dependent calcium mobilization (see Calcium mobilization) (15, 16).

Lipid-lowering effects with pharmacologic doses of nicotinic acid

For over half a century, pharmacologic doses of nicotinic acid, but not nicotinamide, have been known to reduce serum cholesterol (see Disease Treatment) (17). However, the exact mechanisms underlying the lipid-lowering effect of nicotinic acid remain speculative. Two G-protein-coupled membrane receptors, GPR109A and GPR109B, bind nicotinic acid with high and low affinity, respectively. These nicotinic acid receptors are primarily expressed in adipose tissue and immune cells (but not lymphocytes). They are also found in retinal pigmented and colonic epithelial cells, keratinocytes, breast cells, microglia, and possibly at low levels in the liver (18). Thus, lipid-modifying effects of nicotinic acid are likely to be mediated by receptor-independent mechanisms in major tissues of lipid metabolism like liver and skeletal muscle. Early *in vitro* data suggested that nicotinic acid could impair very-low-density lipoprotein (VLDL) secretion by inhibiting triglyceride synthesis and triggering ApoB lipoprotein degradation in hepatocytes (19). In another study, nicotinic acid affected the hepatic uptake of ApoAI lipoprotein, thereby reducing high-density lipoprotein (HDL) removal from the circulation (reviewed in 20). In adipocytes, the binding of nicotinic acid to GPR109A was found to initiate a signal transduction cascade resulting in reductions in free fatty acid production via the inhibition of hormone-sensitive lipase involved in triglyceride lipolysis (21). Nonetheless, recent observations have suggested that the lipid-lowering effect of nicotinic acid was not due to its anti-lipolytic activity (22). Trials showed that synthetic agonists of GPR109A acutely lowered free fatty acids yet failed to affect serum lipids (22). Aside from its impact on HDL and other plasma lipids, nicotinic acid has exhibited anti-atherosclerotic activities in cultured monocytes, macrophages, or vascular endothelial cells, by modulating inflammation and oxidative stress and regulating cell adhesion, migration, and differentiation (reviewed in 18).

Deficiency

Pellagra

Causes

The late stage of severe niacin deficiency is known as pellagra. Early records of pellagra followed the widespread cultivation of corn in Europe in the 1700s (23). The disease is generally associated with poorer social classes whose chief dietary staple consisted of cereal like corn or sorghum. Pellagra was also common in the southern United States during the early 1900s where income was low and corn products were a major dietary staple (24). Interestingly, pellagra was not known in Mexico, where corn was also an important dietary staple and much of the population was also poor. In fact, if corn contains appreciable amounts of niacin, it is present in a bound form that is not nutritionally available to humans. The traditional preparation of corn tortillas in Mexico involves soaking the corn in a lime (calcium oxide) solution, prior to cooking. Heating the corn in an alkaline solution results in the release of bound niacin, increasing its bioavailability (25). Pellagra epidemics were also unknown to Native Americans who consumed immature corn that contains predominantly unbound (bioavailable) niacin (24).

Niacin deficiency or pellagra may result from inadequate dietary intake of NAD precursors, including tryptophan. Niacin deficiency — often associated with malnutrition — is observed in the homeless population, in individuals suffering from anorexia nervosa or obesity, and in consumers of diets high in maize and poor in animal protein (26-29). Deficiencies of other B vitamins and some trace minerals may aggravate niacin deficiency (30, 31). Malabsorptive disorders that can lead to pellagra include Crohn's disease and megaduodenum (32, 33). Patients with Hartnup's disease, a hereditary disorder resulting in defective tryptophan absorption, have developed pellagra (see Niacin-responsive genetic disorders). Carcinoid syndrome, a condition of increased secretion of serotonin and other catecholamines by carcinoid tumors, may also result in pellagra due to increased utilization of dietary tryptophan for serotonin rather than niacin synthesis. Further, prolonged treatment with the anti-tuberculosis drug isoniazid has resulted in niacin deficiency (34). Other pharmaceutical agents, including the immunosuppressive drugs azathioprine (Imuran) and 6-mercaptopurine, the anti-cancer drug 5-fluorouracil (5-FU, Adrucil), and levodopa/carbidopa (Sinemet; two drugs given to people with Parkinson's disease), are known to increase the reliance on dietary niacin by interfering with the tryptophan-kynurenine-niacin pathway (35). Finally, other populations at risk for niacin deficiency include dialysis patients, cancer patients (36, 37), individuals suffering from chronic alcoholism (38), and people with HIV (see HIV/AIDS below). Further, chronic alcohol intake can lead to severe niacin deficiency through reducing dietary niacin intake and interfering with the tryptophan-to-NAD conversion (30).

Symptoms of deficiency

The most common symptoms of niacin deficiency involve the skin, the digestive system, and the nervous system. The symptoms of pellagra are commonly referred to as the three "Ds": sun-sensitive dermatitis, diarrhea, and dementia. A fourth "D," death, occurs if pellagra is left untreated (5). In the skin, a thick, scaly, darkly pigmented rash develops symmetrically in areas exposed to sunlight. In fact, the word "pellagra" comes from "*pelle agra*," the Italian phrase for rough skin. Symptoms related to the digestive system include inflammation of the mouth and tongue ("bright red tongue"), vomiting, constipation, abdominal pain, and ultimately, diarrhea. Gastrointestinal disorders and diarrhea contribute to the ongoing malnourishment of the patients. Neurologic symptoms include headache, apathy, fatigue, depression, disorientation, and memory loss and are more consistent with delirium than with the historically described dementia (38). Disease presentations vary in appearance since the classic triad rarely presents in its entirety. The absence of dermatitis, for example, is known as pellagra *sine* pellagra.

Treatment

To treat pellagra, the World Health Organization (WHO) recommends administering nicotinamide to avoid the flushing commonly caused by nicotinic acid (see Safety). Treatment guidelines suggest using 300 mg/day of oral nicotinamide in divided doses, or 100 mg/day administered parenterally in divided doses, for three to four weeks (37, 39). Because patients with pellagra often display additional vitamin deficiencies, administration of a vitamin B-complex preparation is advised (39).

The Recommended Dietary Allowance (RDA)

Niacin equivalent (NE)

The term "niacin equivalent" (NE) is used to describe the contribution to dietary intake of all the forms of niacin that are available to the body. In healthy individuals, less than 2% of dietary tryptophan is converted to NAD in the kynurenine pathway (40). The synthesis of NAD from tryptophan is fairly inefficient and depends on enzymes requiring vitamin B_6 and riboflavin, as well as a heme (iron)-containing enzyme. Nonetheless, tryptophan is essential as a precursor for NAD^+. Inherited defects in tryptophan transport and metabolism result in severe clinical disorders attributed to NAD^+ depletion (see Niacin-responsive genetic disorders). On average, 60 milligrams (mg) of tryptophan are considered to correspond to 1 mg of niacin or 1 mg of NE.

Daily recommended intakes

The recommended dietary allowance (RDA) for niacin is based on the prevention of deficiency. Pellagra can be prevented by about 11 mg NE/day, but 12 mg to 16 mg NE/day has been found to normalize the urinary excretion of niacin metabolites (breakdown products) in healthy young adults. Because pellagra represents severe deficiency, the Food and Nutrition Board (FNB) of the US Institute of Medicine chose to use the excretion of niacin metabolites as an indicator of niacin nutritional status rather than symptoms of pellagra (41). However, it has been argued that cellular NAD and NADP content may be more relevant indicators of niacin nutritional status (24).

Table 1. Recommended Dietary Allowance (RDA) for Niacin

Life Stage	Age	Males (mg NE*/day)	Females (mg NE/day)
Infants	0-6 months	2 (AI)	2 (AI)
Infants	7-12 months	4 (AI)	4 (AI)
Children	1-3 years	6	6
Children	4-8 years	8	8
Children	9-13 years	12	12
Adolescents	14-18 years	16	14
Adults	19 years and older	16	14
Pregnancy	all ages	-	18
Breast-feeding	all ages	-	17
*NE, niacin equivalent: 1 mg NE = 60 mg of tryptophan = 1 mg niacin			

Disease Prevention

Cancer

Studies of cultured cells (*in vitro*) provide evidence that NAD content influences mechanisms that maintain genomic stability. Loss of genomic stability, characterized by a high rate of damage to DNA and chromosomes, is a hallmark of cancer (42). The current understanding is that the pool of NAD is decreased during niacin deficiency and that it affects the activity of NAD-consuming enzymes rather than redox and metabolic functions (43). Among NAD-dependent reactions, poly ADP-ribosylations catalyzed by PARP enzymes (ARTDs) are critical for the cellular response to DNA injury. After DNA damage, PARPs are activated; the subsequent poly ADP-ribosylations of a number of signaling and structural molecules by PARPs were shown to facilitate DNA repair at DNA strand breaks (44). Cellular depletion of NAD has been found to decrease levels of the tumor suppressor protein p53, a target for poly ADP-ribosylation, in human breast, skin, and lung cells (45). The expression of p53 was also altered by niacin deficiency in rat bone marrow cells (46). Impairment of DNA repair caused by niacin deficiency could lead to genomic instability and drive tumor development in rat models (47, 48). Both PARPs and sirtuins have been recently involved in the maintenance of heterochromatin, a chromosomal domain associated with genome stability, as well as in transcriptional gene silencing, telomere integrity, and chromosome segregation during cell division (49, 50). Neither the cellular NAD content nor the dietary intake of NAD precursors necessary for optimizing protective responses following DNA damage has been determined, but both are likely to be higher than that required for the prevention of pellagra.

Bone marrow

Cancer patients often suffer from bone marrow suppression following chemotherapy, given that bone marrow is one of the most proliferative tissues in the body and thus a primary target for chemotherapeutic agents. Niacin deficiency was found to decrease bone marrow NAD and poly-ADP-ribose levels and increase the risk of chemically induced leukemia in rats (51). Conversely, a pharmacologic dose of either nicotinic acid or nicotinamide was able to increase NAD and poly ADP-ribose in bone marrow and decrease the development of leukemia in rats (52). It has been suggested that niacin deficiency often observed in cancer patients could sensitize bone marrow tissue to the suppressive effect of chemotherapy. However, little is known regarding cellular NAD levels and the prevention of DNA damage or cancer in humans. One study in two healthy individuals involved elevating NAD levels in blood lymphocytes by supplementation with 100 mg/day of nicotinic acid for eight weeks. Compared to non-supplemented individuals, the supplemented individuals had reduced DNA strand breaks in lymphocytes exposed to free radicals in a test tube assay (53). However, nicotinic acid supplementation of up to 100 mg/day for 14 weeks in 21 healthy smokers failed to provide any evidence of a decrease in cigarette smoke-induced genetic damage in blood lymphocytes compared to placebo (54). More recently, the frequency of chromosome translocation was used to evaluate DNA damage in peripheral blood lymphocytes of 82 pilots chronically exposed to ionizing radiation, a known human carcinogen. In this observational study, the rate of chromosome aberrations was significantly lower in subjects with higher (28.4 mg/day) compared to lower (20.5 mg/day) dietary niacin intake (55). Higher availability of NAD^+ in X-irradiated peripheral blood lymphocytes was found to favor DNA repair by enhancing survival, particularly through SIRT-mediated p53 deacetylation (56).

Upper digestive tract

Generally, relationships between dietary factors and cancer are established first in epidemiological studies and followed up by basic cancer research at the cellular level. In the case of niacin, research on biochemical and cellular aspects of DNA repair has stimulated an interest in the relationship between niacin intake and cancer risk in human populations (57). A large case-control study found increased consumption of niacin, along with antioxidant nutrients, to be associated with decreased incidence of oral (mouth), pharyngeal (throat), and esophageal cancers in northern Italy and Switzerland. An increase in daily niacin intake of 6.2 mg was associated with about a 40% decrease in cases of cancers of the mouth and throat, while a 5.2 mg increase in daily niacin intake was associated with a similar decrease in cases of esophageal cancer (58, 59).

Skin

Niacin deficiency can lead to severe sunlight sensitivity in exposed skin. Given the implication of NAD-dependent enzymes in DNA repair, there has been some interest in the effect of niacin on skin health. *In vitro* and animal experiments have helped gather information, but human data on niacin/NAD status and skin cancer are very limited. One study reported that niacin supplementation decreased the risk of ultraviolet light (UV)-induced skin cancers in mice, despite the fact that mice convert tryptophan to NAD more efficiently than rats and humans and thus do not get severely deficient (60). Hyper-proliferation and impaired differentiation of skin cells can alter the integrity of the skin barrier and increase the occurrence of pre-malignant and malignant skin conditions. A protective effect of niacin was suggested by topical application of myristyl nicotinate, a niacin derivative, which successfully increased the expression of epidermal differentiation markers in subjects with photodamaged skin (61). The activation of the nicotinic acid receptors, GPR109A and GPR109B, by pharmacologic doses of niacin could be involved in improving skin barrier function. Conversely, differentiation defects in skin cancer cells were linked to the abnormal cellular localization of defective nicotinic acid receptors (62). Nicotinamide restriction with subsequent depletion of cellular NAD was shown to increase oxidative stress-induced DNA damage in a precancerous skin cell model, implying a protective role of NAD-dependent pathways in cancer (63). Altered NAD availability also affects sirtuin expression and activity in UV-exposed human skin cells. Along with PARPs, NAD-consuming sirtuins could play an important role in the cellular response to photodamage and skin homeostasis (64).

A pooled analysis of two large US prospective cohort studies that followed 41,808 men and 72,308 women for up to 26 years suggested that higher versus lower intake of niacin (from diet and supplements) might be protective against squamous-cell carcinoma but not against basal-cell carcinoma and melanoma (65). A phase III, randomized, double-blind, placebo-controlled trial in 386 subjects with a history of nonmelanoma skin cancer recently examined the effect of daily nicotinamide supplementation (1 g) for 12 months on skin cancer recurrence at three-month intervals over an 18-month period (66). Nicotinamide effectively reduced the rate of premalignant actinic keratose (-11%), squamous-cell carcinoma (-30%), and basal-cell carcinoma (-20%) compared to placebo after 12 months, yet this protection was not sustained during the six-month post-supplementation period (66). Larger trials are needed to assess whether nicotinamide could reduce the risk of melanomas, which are not as common as other skin cancer but are more deadly (67).

Type 1 diabetes mellitus

Type 1 diabetes mellitus in children is caused by the autoimmune destruction of insulin-secreting β-cells in the pancreas. Prior to the onset of symptomatic diabetes, specific antibodies, including islet cell autoantibodies (ICA), can be detected in the blood of high-risk individuals (68). In an experimental animal model of diabetes, high levels of nicotinamide are administered to protect β-cells from damage caused by streptozotocin (69).

Yet, pharmacologic doses of nicotinamide (up to 3 g/day) have not been found to be effective in delaying or preventing the onset of type 1 diabetes in at-risk subjects. An analysis of 10 trials, of which five were placebo-controlled, found evidence of improved β-cell function after one year of treatment with nicotinamide, but the analysis failed to find any clinical evidence of improved glycemic control (70). A large, multicenter randomized controlled trial of nicotinamide in ICA-positive siblings (ages, 3-12 years) of type 1 diabetic patients also failed to find a difference in the incidence of type 1 diabetes after three years (70). A randomized, double-blind, placebo-controlled multicenter trial of nicotinamide (maximum of 3 g/day) was conducted in 552 ICA-positive relatives of patients with type 1 diabetes. The proportion of relatives who developed type 1 diabetes within five years was comparable whether they were treated with nicotinamide or placebo (71). Nicotinamide could reduce inflammation-related parameters in these high-risk subjects yet was ineffective to prevent disease onset (72). More recently, case reports of the combined use of nicotinamide (25 mg/kg/day) and acetyl-L-carnitine (50 mg/kg/day) in children at risk for type 1 diabetes showed promising results, warranting further investigation (73).

Disease Treatment

Niacin supplements at pharmacologic doses (i.e., doses much larger than those needed to prevent deficiency) have been used in an attempt to treat a range of conditions, some of which are discussed below.

Niacin-responsive genetic disorders

Congenital NAD deficiency-related disorders can result from mutations in genes involved in the uptake and transport of the various dietary NAD^+ precursors or in the distinct metabolic pathways leading to NAD^+ production (see Metabolism). Some of these disorders might respond to niacin supplementation. For example, defective transport of tryptophan into cells results in Hartnup disease, which features signs of severe niacin deficiency (74). Hartnup disease is due to mutations in the *SLCA19* gene, which codes for a sodium-dependent neutral amino acid transporter expressed primarily in the kidneys and intestine. Disease management involves supplementation with nicotinic acid or nicotinamide (75). Recessive mutations in genes coding for enzymes of the kynurenine pathway — namely kynureninase and 3-hydroxyanthranilic-acid 3,4-dioxygenase — lead to combined vertebral, anal, cardiac, tracheo-esophageal, renal, and limb (VACTERL) congenital malformations (76). Depletion of NAD^+, rather than accumulation of intermediate metabolites in the kynurenine pathway, was found to be responsible for these malformations. Niacin supplementation throughout pregnancy ensured adequate levels of NAD^+ and prevented congenital anomalies in mice with kynurenine pathway mutations (76). In humans, the dose of NAD^+ precursors necessary to avert NAD deficiency-induced congenital VACTERL malformations has yet to be defined (77).

Nicotinamide may also rescue NAD^+ depletion secondary to an ultra-rare inborn error of glutamine metabolism (78). Glutamine is required for the conversion of nicotinic acid adenine dinucleotide to NAD^+ catalyzed by NAD^+ synthetase (**Figure 2**). Thus, inherited glutamine synthetase deficiency specifically affects the synthesis of NAD^+ from the NAD^+ precursors, tryptophan and nicotinic acid. If the combined deficiencies of glutamine and NAD^+ are responsible for the severe clinical phenotype of subjects with inherited glutamine synthetase deficiency, it is likely that supplementation with both glutamine and nicotinamide would provide some relief (78).

Finally, many inborn errors of metabolism result from genetic mutations decreasing cofactor binding affinity and, subsequently, enzyme efficiency (79). In many cases, the administration of high doses of the vitamins serving as precursors of cofactors can restore enzymatic activity — at least partially — and lessen signs of the genetic diseases (79). Given the large number of enzymes requiring NAD, it is speculated that many of the conditions due to defective enzymes might be rescued by niacin supplementation (5).

Cardiovascular disease

Cardiovascular risk factors

Nicotinic acid is a well-known lipid-lowering agent: Nicotinic acid therapy markedly increases high-density lipoprotein (HDL) cholesterol concentrations, decreases serum lipoprotein(a) concentrations, and shifts small, dense low-density lipoprotein (LDL) particles to large, buoyant LDL particles. All of these changes in the blood lipid profile are considered cardioprotective. Low concentrations of HDL-cholesterol are one major risk factor for coronary heart disease (CHD), and an increase in HDL concentrations is associated with a reduction of that risk (80). Because of the adverse side effects associated with high doses of nicotinic acid (see Safety), nicotinic acid has most often been used in combination with other lipid-lowering medications at slightly lower doses (17). In particular, low-dose nicotinic acid is often co-administered with 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors (statins), the cornerstone of treatment of hyperlipidemia, a major risk factor for CHD. A placebo-controlled study in 39 patients taking statins (cerivastatin, atorvastatin, or simvastatin) found that a very low dose of nicotinic acid (100 mg/day) increased HDL-cholesterol by only 2.1 mg/dL, and the combination had no effect on LDL-cholesterol, total cholesterol, or triglyceride concentrations (81).

The Arterial Biology for the Investigation of the Treatment Effects of Reducing Cholesterol (ARBITER) 2 study — a double-blind, placebo-controlled trial — investigated the incremental effect of adding nicotinic acid (1 g/day) to statin therapy in 167 patients with known CHD and low HDL concentrations on carotid intima-media thickness (CIMT) (82), a surrogate endpoint for the development of atherosclerosis. The addition of extended-release nicotinic acid to simvastatin prevented the increase in CIMT compared to simvastatin monotherapy. A post-hoc analysis of data from ARBITER2 showed that the blockade of atherosclerotic progression was related to the increase in HDL concentrations in patients with normal glycemic status. However, in the presence of additional risk factors, such as impaired fasting glucose or diabetes mellitus, the increase in HDL concentrations was not predictive of CIMT reduction and atherosclerotic retardation (83). A comparative efficacy trial (ARBITER6) also showed a significant reduction of baseline CIMT with extended-release nicotinic acid (2 g/day for 14 months), as opposed to ezetimibe (a cholesterol-lowering drug), in patients taking statins (84).

Additional studies have examined the impact of nicotinic acid on endothelium-dependent brachial flow-mediated dilation (FMD) in patients at risk of CHD or with established CHD. The measurement of FMD is often used as a surrogate marker of endothelial function; FMD values are inversely correlated with the risk of future cardiovascular events (85). A meta-analysis of seven randomized controlled trials, including 441 participants, showed a significant, 2% increase with nicotinic acid (1-2 g/day) administered for 12 weeks to one year (86).

Cardiovascular events

Several randomized, placebo-controlled, multicenter trials have investigated the efficacy and safety of nicotinic acid therapy, alone or in combination with other lipid-lowering agents, on outcomes of cardiovascular disease (CVD). Specifically, the Coronary Drug Project (CDP) followed over 8,000 men with a previous myocardial infarction for six years (87). Compared to the placebo group, patients who took 3 g of immediate-release nicotinic acid daily experienced an average 10% reduction in total blood cholesterol, a 26% decrease in triglycerides, a 27% reduction in recurrent nonfatal myocardial infarction, and a 26% reduction in cerebrovascular events (stroke and transient ischemic attacks). In addition, nine-year follow-up post-trial revealed a 10% reduction in total deaths with nicotinic acid treatment.

The HDL-Atherosclerosis Treatment Study (HATS), a three-year randomized controlled trial in 160 patients with documented CHD and low HDL concentrations, found that a combination of simvastatin and nicotinic acid (2-3 g/day) increased HDL concentrations, inhibited the progression of coronary artery stenosis (narrowing), and decreased the frequency of cardiovascular events, including myocardial infarction and stroke, compared to placebo (88). A subgroup analysis of the HATS patients with metabolic syndrome showed a reduction in rate of primary clinical events even though glucose and insulin metabolism were moderately impaired by nicotinic acid (89). Moreover, a review of nicotinic acid safety and tolerability among the HATS subjects showed glycemic control in diabetic patients returned to pretreatment values following eight months of disease management with medication and diet (90). Similarly, the cardiovascular benefit of long-term nicotinic acid therapy outweighed the modest increase in risk of newly onset type 2 diabetes in patients from the CDP study (91).

In contrast, the AIM-HIGH (Atherothrombosis intervention in metabolic syndrome with low HDL/high triglycerides: impact on global health outcomes) trial, which examined the incremental effect of extended-release nicotinic acid (1.5-2 g/day) on 3,414 patients who had established CVD and atherogenic dyslipidemia and were treated with simvastatin (+/- ezetimibe), provided disappointing results. Indeed, in these patients who had achieved target concentrations of LDL-cholesterol (<70 mg/dL) before randomization, the HDL-raising effect of nicotinic acid treatment failed to reduce the number of cardiovascular events after a mean follow-up of three years (92, 93). While some limitations, like a greater use of simvastatin and ezetimibe in the control group, may have confounded the results, it was also suggested that low HDL-cholesterol might be a marker of risk rather than a causal risk factor for predicting CVD (93). In addition, a post-hoc analysis of 505 participants with stage 3 chronic kidney disease found an increase in all-cause mortality in those randomized to nicotinic acid compared to those in the placebo group (94).

Although nicotinic acid failed to reduce the number of cardiovascular events in simvastatin-treated patients with low LDL-cholesterol, these results cannot be extrapolated to patients with higher LDL-cholesterol at baseline. A much larger multicenter, randomized, double-blind, placebo-controlled trial — the HPS2-THRIVE (Heart protection study 2: treatment of HDL to reduce the incidence of vascular events) trial — in 25,673 participants with vascular disease examined the incremental effect of extended-release nicotinic acid (2 g/day) and laropiprant (a prostaglandin D2 receptor-1 antagonist; 40 mg/day) on the incidence of vascular events. Compared to placebo, nicotinic acid/laropiprant reduced LDL-cholesterol by an average of 10 mg/dL, decreased triglycerides by 33 mg/dL, and increased HDL-cholesterol by 6 mg/dL after a median 3.9-year follow-up period. Nonetheless, nicotinic acid/laropiprant showed no effect on the incidence of major vascular events and death of any cause (95).

A recent meta-analysis of 23 randomized controlled trials — including the CDP, AIM-HIGH, and HPS2-THRIVE trials — in 39,195 subjects with a history of vascular disease compared the effect of nicotinic acid alone or as an add-on to other lipid-lowering agents. No cardiovascular benefits were associated with nicotinic acid therapy: the number of fatal and non-fatal myocardial infarctions and strokes was not decreased with nicotinic acid supplementation (median dose of 2 g/day for a median period of 11.5 months) (96).

Despite the lack of evidence for a role of nicotinic acid in CVD prevention (96, 97), the use of nicotinic acid therapy has rapidly increased over the years in the US (98).

Friedreich's ataxia

Friedreich's ataxia, a common form of inherited ataxia, is an early onset recessive disorder with clinical features that includes progressive ataxia, scoliosis, dysarthria, cardiomyopathy, and diabetes mellitus (99). Most affected subjects carry homozygous guanine-adenine-adenine (GAA) repeat expansions in the first intron of the gene *FXN* coding for the protein frataxin. These abnormal and unstable GAA repeats trigger gene silencing through heterochromatin formation, leading to significantly reduced frataxin expression (100). Frataxin is a mitochondrial protein needed for the making of iron-sulfur clusters (ISC). ISC-containing subunits are especially important for the mitochondrial respiratory chain and for the synthesis of heme-containing proteins (99).

Predominantly localized in the nucleus, SIRT1 is a NAD^+-dependent deacetylase that promotes gene silencing through heterochromatin formation. Nicotinamide has been shown to antagonize heterochromatization of the *FXN* locus and upregulate frataxin expression in lymphoblastoid cells derived from Friedreich's ataxia-affected patients, possibly through inhibiting SIRT1 activity (100). In an open-label, dose escalating pilot trial in 10 adult patients with Friedreich's ataxia, single and repeated doses of nicotinamide (2-8 g) for up to eight weeks were found to be well tolerated (101). Repeated daily doses of 3.5 to 6 g of nicotinamide led to significant increases in frataxin concentration in peripheral white blood cells (101). Yet, no neurological improvements were reported, suggesting that the duration of the treatment was too short and/or the nervous system of the participants was unresponsive to increases in frataxin (102). To our knowledge, there is currently no ongoing trial designed to further investigate the effect of nicotinamide in Friedreich's ataxia-affected patients.

HIV/AIDS

The first step in the kynurenine pathway is catalyzed by the extrahepatic enzyme, indoleamine 2,3-dioxygenase (IDO), which is responsible for the oxidative cleavage of tryptophan. The chronic stimulation of tryptophan oxidation, mediated by an increased activity of IDO and/or inadequate dietary niacin intakes, is observed with the infection of human immunodeficiency virus (HIV), the virus that causes acquired immunodeficiency syndrome (AIDS). Interferon-gamma (IFN-γ) is a cytokine produced by cells of the immune system in response to infection. Through stimulating the enzyme IDO, IFN-γ increases the breakdown of tryptophan, thus supporting the finding that the average tryptophan concentration in blood is significantly lower in HIV patients compared to uninfected subjects (40). An increased degradation of tryptophan via the kynurenine pathway appears to coexist with intracellular niacin/NAD deficiency in HIV infection (103). An explanatory model for these paradoxical observations incriminates the oxidative stress induced by multiple nutrient deficiencies in HIV patients (103). In particular, the activation of PARP enzymes (ARTDs) by oxidative damage to DNA could be responsible for inducing niacin/NAD depletion (see Function). The breakdown of tryptophan would then be a compensatory response to inadequate niacin/NAD levels.

However, metabolites derived from the oxidation of tryptophan in the kynurenine pathway regulate specific T-lymphocyte subgroups. As mentioned above, circulating IFN-γ, but also viral and bacterial products, can activate IDO during HIV infection. The overstimulation of the tryptophan pathway has been involved in the loss of normal T-lymphocyte function, which characterizes HIV infection (104, 105). The increased IDO activity has been linked to the altered immune response that contributes to the persistence of HIV (104). Antiretroviral therapy (ART) only partially restores normal IDO activity, without normalizing it, yet induces viral suppression and CD4 T-cell recovery (106). In a monkey model for HIV infection, a partial and transient blockade of IDO with IDO inhibitor 1-methyl tryptophan proved ineffective to reduce the viral load in plasma and intestinal tissues beyond the level achieved by ART (107). At present, a better understanding of the role of kynurenine pathway and other NAD biosynthetic pathways during HIV infection is needed before the relevance and clinical implications of niacin supplementation in HIV treatment could be considered.

Nonetheless, pharmacologic doses of nicotinic acid have been shown to be well tolerated in HIV patients with hyperlipidemia (108). Abnormal lipid profiles observed in patients have been attributed to the HIV infection and to the highly active antiretroviral treatment (HAART) (109). Moreover, insulin resistance has been detected together with dyslipidemia in ART-treated patients (110). Cardiovascular disease (CVD) is the second most frequent cause of deaths in the HIV population, and the rate of CVD is predicted to increase further as patients are living longer due to successful antiretroviral therapies. As for the general population, statin-based therapy appears to benefit HIV patients in terms of atherogenic protection and CVD risk reduction, although contraindications exist due to drug interactions with ART. Other first-line treatments include lipid-lowering fibrates, which are preferred to nicotinic acid due to the increased risk of glucose intolerance and insulin resistance (111). Nevertheless, an unblinded, controlled pilot study showed that extended-release nicotinic acid (0.5-1.5 g/day for 12 weeks) could effectively improve endothelial function of the brachial artery in ART-treated HIV subjects with low HDL-cholesterol and no history of CVD (112). In addition, a combined treatment of fibrates, extended-release nicotinic acid (0.5-2 g/day), and lifestyle changes (low-fat diet and exercise) for 24 weeks was effective in normalizing lipid parameters in a cohort of 191 ART-treated patients. Increased risk of liver dysfunction was detected in subjects receiving both fibrates and niacin, but insulin sensitivity was not affected by nicotinic acid treatment given alone or when combined with fibrates (113). Another 24-week, open-label, uncontrolled trial in 99 ART-treated patients found that randomization to extended-release nicotinic acid (0.5-2 g/day) or fenofibrates increased blood HDL-cholesterol but did not reduce inflammatory markers or improve endothelial function when compared to baseline (114).

Schizophrenia

Schizophrenia is a neurologic disorder with unclear etiology that is diagnosed purely from its clinical presentation. Because neurologic disorders associated with pellagra resemble acute schizophrenia, niacin-based therapy for the condition was investigated during the 1950s-70s (reviewed in 115). The adjunctive use of nutrients like niacin to correct deficiencies associated with neurologic symptoms is called orthomolecular psychiatry (116). Such an approach has not been included in psychiatric practice; practitioners have instead relied solely on antipsychotic drugs to eliminate the clinical symptoms of schizophrenia. Nevertheless, recent scientific advances and new hypotheses on the benefit of nutrient supplementation in the treatment of psychiatric disorders have suggested the re-assessment of orthomolecular medicine by the medical community (117, 118).

Skin flushing is one major side effect of the therapeutic use of nicotinic acid and the primary reason for non-adherence to treatment (see Toxicity). Flushing is caused by the activation of phospholipase A2, an enzyme that stimulates the production of a specific lipid from the prostanoid family called prostaglandin D2. Prostaglandin D2, synthesized by antigen-presenting cells of the skin and mucosa (i.e., the Langerhans cells), can induce the dilation of blood vessels and trigger a flushing response. Interestingly, patients with schizophrenia tend not to flush following treatment with nicotinic acid. This blunted skin flushing response suggests abnormal prostanoid signaling in schizophrenic patients (119, 120). An association has been found between the altered niacin sensitivity and greater functional impairment in schizophrenic subjects (121), which supports other findings suggesting that altered lipid metabolism could critically impair brain development and contribute to the disease (122). Interestingly, blunted skin flushing responses are more prevalent in first-degree relatives of people with schizophrenia than in the general population, suggesting that reduced niacin sensitivity is a heritable trait within affected families (123).

Sources

Food sources

Good sources of niacin include yeast, meat, poultry, red fish (e.g., tuna, salmon), cereal (especially fortified cereal), legumes, and seeds. Milk, green leafy vegetables, coffee, and tea also provide some niacin (124). In plants, especially mature cereal grains like corn and wheat, niacin may be bound to sugar molecules in the form of glycosides, which significantly decrease its bioavailability (25).

In the United States, the average dietary intake of niacin is about 30 mg/day for young adult men and 20 mg/day for young adult women. In a sample of adults over the age of 60, men and women were found to have an average dietary intake of 21 mg/day and 17 mg/day, respectively (41). Some foods with substantial amounts of niacin are listed in **Table 2**, along with their niacin content in milligrams (mg). Food composition tables generally list niacin content without including niacin equivalents (NE) from tryptophan or any adjustment for niacin bioavailability. For more information on the nutrient content of specific foods, search USDA's FoodData Central database; data included in **Table 2** are from this database (125).

Table 2. Some Food Sources of Niacin

Food	Serving	Niacin (mg)
Chicken (light meat, cooked without skin)	3 ounces*	8.9
Tuna (light, canned, packed in water)	3 ounces	8.6
Turkey (light meat, cooked without skin)	3 ounces	9.9
Salmon (chinook, cooked)	3 ounces	8.5
Beef (90% lean, cooked)	3 ounces	4.4
Cereal (unfortified)	1 cup	5-7
Cereal (fortified)	1 cup	20-27
Peanuts (dry-roasted)	1 ounce	4.1
Pasta (enriched, cooked)	1 cup	1.9-2.4
Lentils (cooked)	1 cup	2.1
Lima beans (cooked)	1 cup	0.8
Bread (whole-wheat)	1 slice	1.4
Coffee (brewed)	1 cup	2
*A three-ounce serving of meat is about the size of a deck of cards.		

Supplements

Niacin supplements are available as nicotinamide or nicotinic acid. Nicotinamide is the form of niacin typically used in nutritional supplements and in food fortification. Nicotinic acid is available over the counter and with a prescription as a cholesterol-lowering agent (126). Nicotinic acid for anti-hyperlipidemic use is available in three formulations: immediate-release (crystalline) nicotinic acid (absorption time, 1-2 hrs), extended-release nicotinic acid (absorption time, 8-12 hrs), and sustained-release nicotinic acid (absorption time, >12 hrs) (127). At the pharmacologic dose required for cholesterol-lowering effects, the use of nicotinic acid should be approached as if it were a drug (see Safety). Individuals should only undertake cholesterol-lowering therapy with nicotinic acid under the supervision of a qualified health care provider in order to minimize potentially adverse effects and maximize therapeutic benefits.

Safety

Toxicity

Nicotinic acid

Common side effects of nicotinic acid include flushing, pruritus (severe itching of the skin), skin rashes, and gastrointestinal disturbances, such as nausea and vomiting (97). Transient episodes of low blood pressure (hypotension) and headache have also been reported. Hepatotoxicity (liver cell damage), including elevated liver enzymes and jaundice, has been observed at intakes as low as 750 mg/day of nicotinic acid (128). Although hepatitis has been observed with extended-release nicotinic acid at dosages as little as 500 mg/day for two months, almost all reports of severe hepatitis have been associated with doses of 3 to 9 g/day used to treat high cholesterol for months or years (41). It is unclear whether immediate-release (crystalline) nicotinic acid is less toxic to the liver than extended-release forms (41). Yet, immediate-release nicotinic acid is often used at higher doses than extended-release forms, and severe liver toxicity has occurred in individuals who substituted extended-release nicotinic acid for immediate-release nicotinic acid at equivalent doses (126). Large doses of nicotinic acid have been observed to impair glucose tolerance, likely because of a decrease in insulin sensitivity. Impaired glucose tolerance in susceptible (pre-diabetic) individuals could result in elevated blood glucose concentrations and clinical type 2 diabetes mellitus. An analysis of the HPS2-THRIVE trial (see Cardiovascular disease), using data from 17,374 participants without type 2 diabetes at baseline, found a significantly higher proportion of newly diagnosed cases among those randomized to nicotinic acid/laropiprant than to placebo (5.7% versus 4.3%) over a 3.9 year-period (95). Likewise, randomization to nicotinic acid/laropiprant significantly increased the risk of serious disturbances in diabetes control (leading to hospitalization) compared to placebo among 8,299 participants with diabetes at baseline (95). Elevated blood concentrations of uric acid, occasionally resulting in attacks of gout in susceptible individuals, have also been observed with high-dose nicotinic acid therapy (126). Niacin at doses of 1.5 to 5 g/day has resulted in a few case reports of blurred vision and other eye problems, which have generally been reversible upon discontinuation (41). People with abnormal liver function or a history of liver disease, diabetes, active peptic ulcer disease, gout, cardiac arrhythmias, inflammatory bowel disease, migraine headaches, or alcoholism may be more susceptible to the adverse effects of excess niacin intake than the general population (41).

Nicotinamide

Nicotinamide is generally better tolerated than nicotinic acid; it does not generally cause flushing (126). However, nausea, vomiting, and signs of liver toxicity (elevated liver enzymes, jaundice) have been observed at very high doses (≥10 g/day) (126).

Nicotinamide riboside

A study in 12 healthy subjects found that nicotinamide riboside at three single doses (100 mg, 300 mg, and 1,000 mg) safely increased blood NAD^+. Two of the participants self-reported skin flushing after taking the 300-mg dose, and two others reported feeling hot following intake of 1,000 mg of nicotinamide riboside (1). In a recent randomized, placebo-controlled trial in 120 healthy adults (ages, 60-80 years), daily supplementation with nicotinamide riboside (250 mg or 500 mg) and pterostilbene (a SIRT activator; 50 mg or 100 mg) for eight weeks showed a favorable side effect profile, with no evidence of higher incidence of adverse effects compared to placebo (129). Most recently, a randomized, placebo-controlled trial in 40 obese men (ages, 40-70 years) found that daily supplementation with nicotinamide riboside (2,000 mg/day divided into two daily dosages) for 12 weeks was associated with reports of only minor side effects, including excessive sweating, pruritus, and mild gastrointestinal symptoms like bloating (139).

The tolerable upper intake level (UL)

Flushing of the skin primarily on the face, arms, and chest is a common side effect of nicotinic acid and may occur initially at doses as low as 30 mg/day. Although flushing from nicotinamide is rare, the Food and Nutrition Board set the tolerable upper intake level (UL) for niacin (nicotinic acid and nicotinamide) at 35 mg/day in adults to avoid the adverse effect of flushing (41). Analysis of data from the US National Health and Nutrition Examination Survey (NHANES) 2003-2006 found that 15.8% of children and adolescents (ages 2-18 years) and 8.5% of adults (≥19 years) had total usual niacin intakes exceeding the UL (130). The UL applies to the general population and is not meant to apply to individuals who are being treated with a nutrient under medical supervision (e.g., high-dose nicotinic acid for elevated blood cholesterol concentrations).

Table 3. Tolerable Upper Intake Level (UL) for Niacin

Age Group	UL (mg/day)
Infants 0-12 months	Not possible to establish*
Children 1-3 years	10
Children 4-8 years	15
Children 9-13 years	20
Adolescents 14-18 years	30
Adults 19 years and older	35
*Source of intake should be from food and formula only.	

Drug interactions

The occurrence of rhabdomyolysis is increased in patients treated with statins (HMG-CoA reductase inhibitors). Rhabdomyolysis is a relatively uncommon condition in which muscle cells are broken down, releasing enzymes and electrolytes into the blood, and sometimes resulting in kidney failure (131). Co-administration of nicotinic acid with a statin seems to enhance the risk of rhabdomyolysis (132). A new drug, laropiprant, blocks prostanoid receptors and reduces nicotinic acid-induced flushing (133). A randomized, placebo-controlled trial was designed to identify possible adverse effects of the niacin/laropiprant combination in over 25,000 simvastatin-treated subjects (134). When added to the statin therapy, niacin/laropiprant increased the risk of myopathy and rhabdomyolysis, particularly in Asian subjects. It is possible that the niacin/laropiprant combination further reduces the poor tolerability to statin treatment observed in certain populations (135).

In the three-year, randomized controlled HATS study, concurrent therapy with antioxidants (1,000 mg/day of vitamin C, 800 IU/day of *RRR*-α-tocopherol, 100 μg/day of selenium, and 25 mg/day of β-carotene) diminished the protective effects of the simvastatin-nicotinic acid combination (136). Although the mechanism for these effects is not known, the benefit of concurrent antioxidant therapy in patients on lipid-lowering agents has been questioned (137).

Adverse effects of large doses of nicotinic acid may be exacerbated by the concomitant use of certain medications. The risk of myopathy may be further increased in those taking nicotinic acid and bile acid sequestrants (e.g., cholestyramine, colestipol) or the anti-lipidemic drug, gemfibrozil (Lopid), and the risk of hepatotoxicity observed with nicotinic acid might be enhanced by drugs like paracetamol, amiodarone (Cordarone), or carbamazepine (Tegretol) (35). In addition, large doses of nicotinic acid may reduce uric acid excretion, thereby opposing the action of uricosuric agents like probenecid (Probalan) (35).

Several other medications may interact with niacin therapy or with absorption and metabolism of the vitamin (126). Estrogen and estrogen-containing oral contraceptives increase the efficiency of niacin synthesis from tryptophan, resulting in a decreased dietary requirement for niacin (138). Long-term administration of chemotherapy agents has been reported to cause symptoms of pellagra; therefore, niacin supplementation may be needed (see Pellagra causes).

Linus Pauling Institute Recommendation

The optimum intake of niacin for health promotion and chronic disease prevention is not yet known. The RDA (16 mg NE/day for men and 14 mg NE/day for women) is easily obtainable by consuming a varied diet and should prevent deficiency in most people. Following the Linus Pauling Institute recommendation to take a daily multivitamin/mineral supplement, containing 100% of the Daily Value (DV) for niacin, will provide at least 20 mg of niacin daily.

Summary

- Pantothenic acid — also known as vitamin B_5 — is a water-soluble vitamin that is a precursor in the synthesis of coenzyme A. Coenzyme A is essential to many biochemical reactions that sustain life. Also, the phosphopantetheinyl moiety of coenzyme A is required for the biological activity of several proteins, including the acyl-carrier protein involved in fatty acid synthesis. *(More information)*
- Pantothenic acid is essential to all forms of life. It is ubiquitously found in foods of plant and animal origin, and dietary deficiency is very rare. *(More information)*
- The Food and Nutrition Board of the US Institute of Medicine set an adequate intake (AI) of 5 milligrams (mg)/day for adults based on the estimated daily average intake of pantothenic acid. *(More information)*
- Evidence from limited intervention studies suggests that pantothenic acid and/or pantothenol (alcohol analog) might improve the healing process of skin wounds. Yet, additional larger studies are warranted. *(More information)*
- Treatment with high-dose pantethine — a pantothenic acid derivative — has been shown to lower serum cholesterol and lipid concentrations. Although pantethine therapy appears to be well tolerated, medical supervision is indispensable. *(More information)*
- Foods rich in pantothenic acid include animal organs (liver and kidney), fish, shellfish, milk products, eggs, avocados, legumes, mushrooms, and sweet potatoes. *(More information)*
- Little or no toxicity has been associated with dietary and supplemental pantothenic acid such that no tolerable upper intake level (UL) has been set. *(More information)*

Pantothenic acid, also known as vitamin B_5, is essential to all forms of life (1). Pantothenic acid is found throughout all branches of life in the form of coenzyme A, a vital coenzyme in numerous chemical reactions (2).

Function

Synthesis of pantothenic acid cofactors

Coenzyme A

Pantothenic acid is a precursor in the biosynthesis of coenzyme A (CoA) (**Figure 1**), an essential coenzyme in a variety of biochemical reactions that sustain life (see below). Pantothenic acid kinase II (PANKII) catalyzes the initial step of phosphorylation of pantothenic acid to 4'-phosphopantothenic acid. Coenzyme A and its derivatives inhibit the synthesis of 4'-phosphopantothenic acid, but the inhibition can be reversed by carnitine, required for the transport of fatty acids into the mitochondria (3). The subsequent reactions in this biosynthetic pathway include the synthesis of the intermediate 4'-phosphopantetheine, as well as the recycling of coenzyme A to 4'-phosphopantetheine (**Figure 1**).

Pantothenic acid is a precursor in the synthesis of coenzyme A. The initial phosphorylation reaction that converts pantothenic acid into 4'-phosphopantothenic acid is impaired in individuals with an inherited defect in the gene (*PANKII*) coding for pantothenic acid kinase II.

4'-phosphopantetheine

The 4'-phosphopantetheinyl moiety of coenzyme A can be transferred to enzymes in which 4'-phosphopantetheine is an essential cofactor for their biological activities (see 4'-phosphopantetheinylation).

Cofactor and co-substrate function

Coenzyme A

Coenzyme A reacts with acyl groups, giving rise to thioester derivatives, such as acetyl-CoA, succinyl-CoA, malonyl-CoA, and 3-hydroxy-3-methylglutaryl (HMG)-CoA. Coenzyme A and its acyl derivatives are required for reactions that generate energy from the degradation of dietary fat, carbohydrates, and proteins. In addition, coenzyme A in the form of acetyl-CoA and succinyl-CoA is involved in the citric acid cycle, in the synthesis of essential fats, cholesterol, steroid hormones, vitamins A and D, the neurotransmitter acetylcholine, and in the fatty acid β-oxidation pathway. Coenzyme A derivatives are also required for the synthesis of the hormone, melatonin, and for a component of hemoglobin called heme. Further, metabolism of a number of drugs and toxins by the liver requires coenzyme A (4).

Coenzyme A was named for its role in acetylation reactions. Most acetylated proteins in the body have been modified by the addition of an acetate group that was donated by the coenzyme A thioester derivative, acetyl-CoA. Protein acetylation alters the overall charge of proteins, modifying their three-dimensional structure and, potentially, their function. For example, acetylation is a mechanism that regulates the activity of peptide hormones, including those produced by the pituitary gland (5). Also, protein acetylation, like other posttranslational modifications, has been shown to regulate the subcellular localization, the function, and the half-life of many signaling molecules, transcription factors, and enzymes. Notably, the acetylation of histones plays a role in the regulation of gene expression by facilitating transcription (i.e., mRNA synthesis), while deacetylated histones are usually associated with chromatin compaction and gene silencing. The acetylation of histones was found to result in structural changes of the chromatin, which affect both DNA-protein and protein-protein interactions. Crosstalk between acetylation marks and other posttranscriptional modifications of the histones also facilitate the recruitment of transcriptional regulators to the promoter of genes that are subsequently transcribed (reviewed in 6).

Finally, a number of signaling molecules are modified by the attachment of long-chain fatty acids donated by coenzyme A. These modifications are known as protein acylation and have central roles in cell-signaling pathways (4).

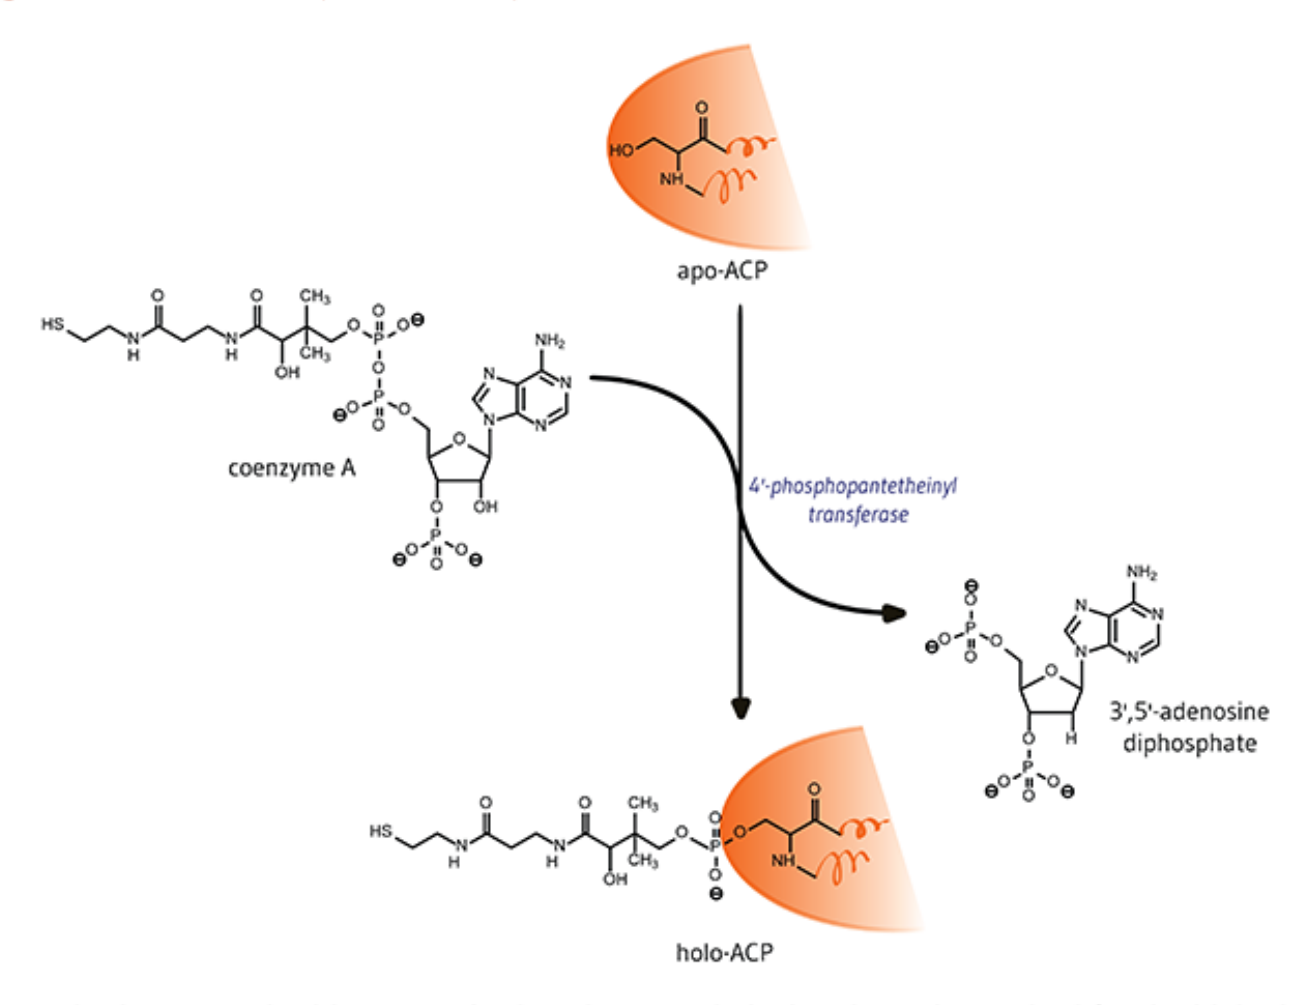
4'-phosphopantetheinylation

Specific multi-enzyme complexes, which need to carry out several reactions in an orderly manner, may require the covalent attachment of a 4'-phosphopantetheine arm to a "carrier" domain (or protein). This carrier domain holds substrates or reaction intermediates during the progression through the various enzymatic reactions. In mammals, the transfer of the 4'-phosphopantetheinyl moiety from coenzyme A to a conserved serine residue of a specific carrier domain is catalyzed by one unique phosphopantetheinyl transferase (7). The 4'-phosphopantetheinylation is necessary for the conversion of apo-enzymes into fully active holo-enzymes (see below).

Acyl-carrier protein

Lipids are fat molecules essential for normal physiological function and, among other types, include sphingolipids (essential components of the myelin sheath that enhances nerve transmission), phospholipids (important structural components of cell membranes), and fatty acids. Fatty acid synthase (FAS) is a multi-enzyme complex that catalyzes the synthesis of fatty acids. Within the FAS complex, the acyl-carrier protein (ACP) requires pantothenic acid in the form of 4'-phosphopantetheine for its activity as a carrier protein (3). A group, such as the 4'-phosphopantetheinyl moiety for ACP, is called a prosthetic group; the prosthetic group is not composed of amino acids and is a tightly bound cofactor required for the biological activity of some proteins (**Figure 2**). Acetyl-CoA, malonyl-CoA, and ACP are all required for the synthesis of fatty acids in the cytosol. During fatty acid synthesis, the acyl groups of acetyl-CoA and malonyl-CoA are transferred to the sulfhydryl group (-SH) of the 4'-phosphopantetheinyl moiety of ACP. The prosthetic group is used as a flexible arm to transfer the growing fatty acid chain to each of the enzymatic centers of the type I FAS complex. In the mitochondria, 4'-phosphopantetheine also serves as a prosthetic group for an ACP homolog present in mitochondrial type II FAS complex (8).

Figure 2. 4'-Pantetheinylation of Acyl-Carrier Protein (ACP)



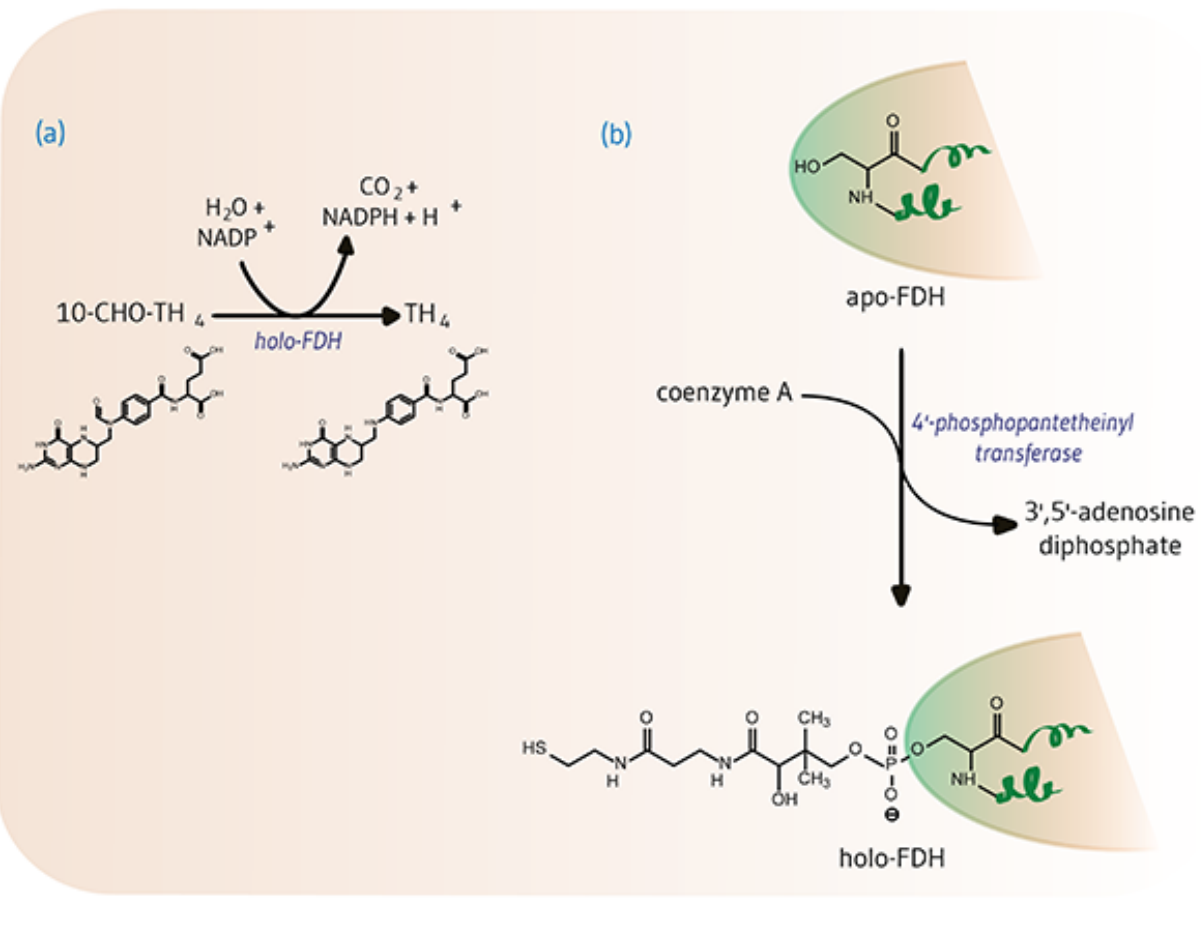
apo-ACP
coenzyme A
4'-phosphopantetheinyl transferase
3',5'-adenosine diphosphate
holo-ACP

A prosthetic group – in this case, a 4'-phosphopantetheinyl moiety – is required for the biological function of ACP. The addition of the prosthetic group occurs after ACP synthesis (post-translation) in a reaction catalyzed by 4'-phosphopantetheinyl transferase. The enzyme catalyzes the hydrolysis of coenzyme A to 3',5'-adenosine diphosphate and 4'-phosphopantetheine, and the transfer of the 4'-phosphopantetheinyl moiety to a serine residue at the active site of ACP. *ACP, acyl-carrier protein; apo-ACP, biologically inactive ACP; holo-ACP, biologically active ACP.*

10-formyltetrahydrofolate dehydrogenase

The enzyme 10-formyltetrahydrofolate dehydrogenase (FDH) catalyzes the conversion of 10-formyltetrahydrofolate to tetrahydrofolate, an essential cofactor in the metabolism of nucleic acids and amino acids (**Figure 3**). Similar to ACP, FDH requires a 4'-phosphopantetheine prosthetic group for its biological activity. The prosthetic group acts as a swinging arm to couple the activities of the two catalytic domains of FDH (9, 10). A homolog of FDH in mitochondria also requires 4'-phosphopantetheinylation to be biologically active (11).

Figure 3. 4'-Pantetheinylation of Formyltetrahydrofolate Dehydrogenase (FDH)



(a) The generation of TH_4 from 10-CHO-TH_4 is catalyzed by FDH, an enzyme requiring 4'-phosphopantetheine as a prosthetic group to be biologically active. Of note, 10-CHO-TH_4 can also be hydrolyzed to TH_4 (and formate) in another reaction catalyzed by formyltetrahydrofolate deformylase. (b) The enzyme 4'-phosphopantetheinyl transferase catalyzes the transfer of a 4'-phosphopantetheinyl moiety from coenzyme A to a specific serine residue of FDH, converting apo-FDH to holo-FDH. *FDH, formyltetrahydrofolate dehydrogenase; apo-FDH, biologically inactive FDH; holo-FDH, biologically active FDH; 10-CHO-TH_4, 10-formyltetrahydrofolate; TH_4, tetrahydrofolate; $NADP^+$/NADPH, nicotinamide adenine dinucleotide phosphate oxidized/reduced.*

α-Aminoadipate semialdehyde synthase

4'-phosphopantetheinylation is required for the biological activity of the apo-enzyme α-aminoadipate semialdehyde synthase (AASS). AASS catalyzes the initial reactions in the mitochondrial pathway for the degradation of lysine — an essential amino acid for humans. AASS is made of two catalytic domains. The lysine-ketoglutarate reductase domain first catalyzes the conversion of lysine to saccharopine. Saccharopine is further converted to α-aminoadipate semialdehyde in a reaction catalyzed by the saccharopine dehydrogenase domain (**Figure 4**).

holo-AASS

AASS is a mitochondrial enzyme responsible for the conversions of lysine to saccharopine and saccharopine to α-aminoadipate semialdehyde in the mitochondrial pathway for lysine degradation. The first reaction is catalyzed by the lysine-ketoglutarate reductase domain of AASS, and the saccharopine dehydrogenase domain catalyzes the second reaction. Apo-AASS requires 4'-phosphopantetheine as a prosthetic group to be biologically active. The enzyme 4'-phosphopantetheinyl transferase catalyzes the transfer of a 4'-phosphopantetheinyl moiety from coenzyme A to a specific residue of AASS, converting apo-AASS to holo-AASS. The 4'-phosphopantetheinyl arm is thought to serve as a swinging arm that couples the activities of the two enzymatic domains of AASS. *AASS, α-aminoadipate semialdehyde synthase.*

Deficiency

Naturally occurring pantothenic acid deficiency in humans is very rare and has been observed only in cases of severe malnutrition. World War II prisoners in the Philippines, Burma, and Japan experienced numbness and painful burning and tingling in their feet; these symptoms were relieved specifically by pantothenic acid supplementation (4). Pantothenic acid deficiency in humans has been induced experimentally by co-administering a pantothenic acid kinase inhibitor (ω-methylpantothenate; see **Figure 1** above) and a pantothenic acid-deficient diet. Participants in this experiment complained of headache, fatigue, insomnia, intestinal disturbances, and numbness and tingling of their hands and feet (12). In another study, participants fed only a pantothenic acid-free diet did not develop clinical signs of deficiency, although some appeared listless and complained of fatigue (13).

Calcium homopantothenate (or hopantenate) is a pantothenic acid antagonist with cholinergic effects (i.e., similar to those of the neurotransmitter, acetylcholine). This compound is used in Japan to enhance mental function, especially in Alzheimer's disease. A rare side effect was the development of hepatic encephalopathy, a condition of abnormal brain function resulting from the failure of the liver to eliminate toxins. The encephalopathy was reversed by pantothenic acid supplementation, suggesting that it was due to homopantothenate-induced pantothenic acid deficiency (14). Of note, genetic mutations in the human gene *PANKII*, which codes for pantothenic acid kinase II (see **Figure 1** above), result in impaired synthesis of 4'-phosphopantetheine and coenzyme A (see Function). The disorder, called pantothenate kinase-associated neurodegeneration, is characterized by visual and intellectual impairments, dystonia, speech abnormalities, behavioral difficulties, and personality disorders (15).

Yet, because pantothenic acid is widely distributed in nature and deficiency is extremely rare in humans, most information regarding the consequences of deficiency has been gathered from experimental research in animals (reviewed in 3). Pantothenic acid-deficient rats developed damage to the adrenal glands, while monkeys developed anemia due to decreased synthesis of heme, a component of hemoglobin. Dogs with pantothenic acid deficiency developed low blood glucose, rapid breathing and heart rates, and convulsions. Chickens developed skin irritation, feather abnormalities, and spinal nerve damage associated with the degeneration of the myelin sheath. Pantothenic acid-deficient mice showed decreased exercise tolerance and diminished storage of glucose (in the form of glycogen) in muscle and liver. Mice also developed skin irritation and graying of the fur, which is reversed by pantothenic acid administration.

The diversity of symptoms emphasizes the numerous functions of pantothenic acid in its coenzyme forms.

The Adequate Intake (AI)

Because there was little information on the requirements of pantothenic acid in humans, the Food and Nutrition Board of the Institute of Medicine set an adequate intake (AI) based on observed dietary intakes in healthy population groups (**Table 1**) (16).

Table 1. Adequate Intake (AI) for Pantothenic Acid

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	1.7	1.7
Infants	7-12 months	1.8	1.8
Children	1-3 years	2	2
Children	4-8 years	3	3
Children	9-13 years	4	4
Adolescents	14-18 years	5	5
Adults	19 years and older	5	5
Pregnancy	all ages	-	6
Breast-feeding	all ages	-	7

Disease Treatment

Wound healing

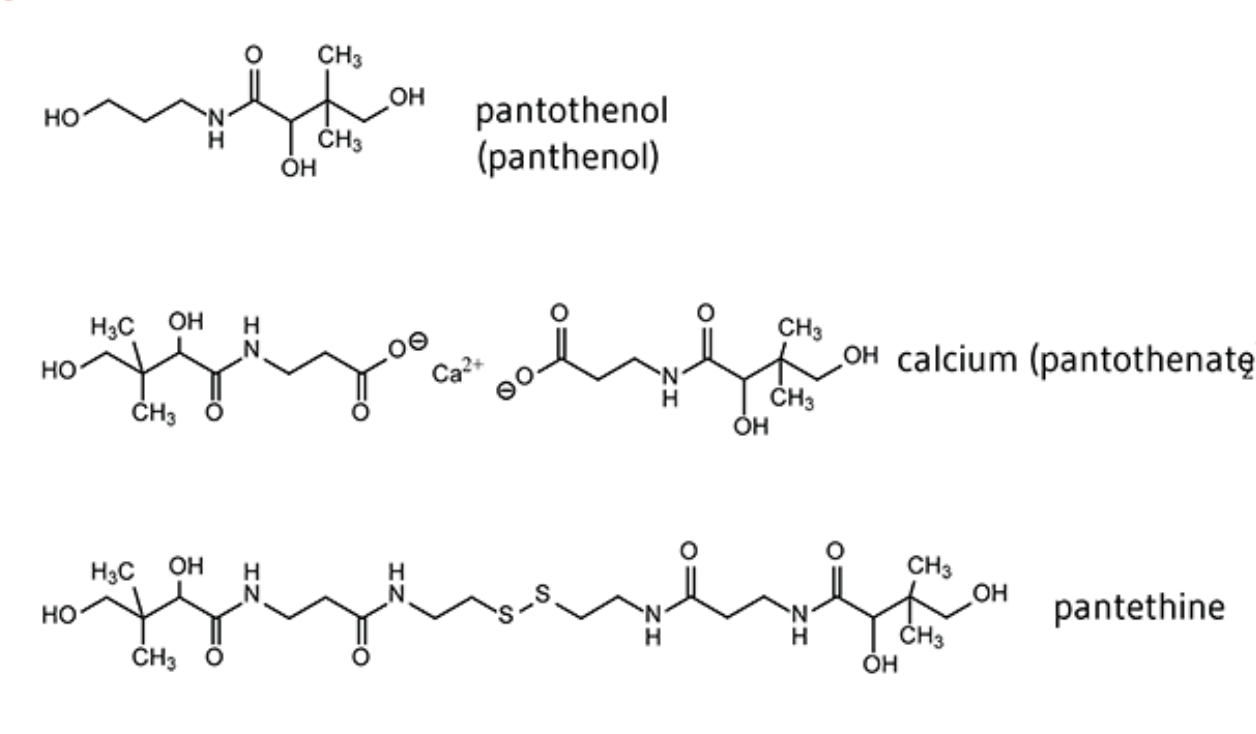
The addition of calcium D-pantothenate and/or pantothenol (**Figure 5**) to the medium of cultured skin fibroblasts given an artificial wound was found to increase cell proliferation and migration, thus accelerating wound healing *in vitro* (17, 18). Likewise, *in vitro* deficiency in pantothenic acid induced the expression of differentiation markers in proliferating skin fibroblasts and inhibited proliferation in human keratinocytes (19). The application of ointments containing either calcium D-pantothenate or pantothenol — also known as D-panthenol or dexpanthenol — to the skin has been shown to accelerate the closure of skin wounds and increase the strength of scar tissue in animals (3).

The effects of dexpanthenol on wound healing are unclear. In a placebo-controlled study that included 12 healthy volunteers, the application of dexpanthenol-containing ointment (every 12 hours for 1 to 6 days) in a model of skin wound healing was associated with an enhanced expression of markers of proliferation, inflammation, and tissue repair (20). However, the study failed to report whether these changes in response to topical dexpanthenol improved the wound-repair process compared to placebo (20). Some studies have shown no effects. Early randomized controlled trials in patients undergoing surgery for tattoo removal found that daily co-supplementation with 1 gram or 3 grams of vitamin C and 200 mg or 900 mg of pantothenic acid for 21 days did not significantly improve the wound-healing process (21, 22). Yet, in a recent randomized, double-blind, placebo-controlled study, the use of dexpanthenol pastilles (300 mg/day for up to 14 days post surgery) was found to accelerate mucosal healing after tonsillectomy in children (23).

High cholesterol

Early studies suggested that pharmacologic doses of pantethine, a pantothenic acid derivative, might have a cholesterol-lowering effect (24, 25). Pantethine is made of two molecules of pantetheine joined by a disulfide bond (chemical bond between two molecules of sulfur) (**Figure 5**). Pantethine is structurally related to coenzyme A and is found in the prosthetic group that is required for the biological function of acyl-carrier protein, formyltetrahydrofolate dehydrogenase, and α-aminoadipate semialdehyde synthase (see Function). In a 16-week, randomized, double-blind, placebo-controlled study, daily pantethine supplementation (600 mg/day for 8 weeks, followed by 900 mg/day for another 8 weeks) significantly improved the profile of lipid parameters in 120 individuals at low-to-moderate risk of cardiovascular disease (CVD). After adjusting to baseline, pantethine was found to be significantly more effective than placebo in lowering the concentrations of low-density lipoprotein-cholesterol (LDL-C) and apolipoprotein B (apoB), as well as reducing the ratio of triglycerides to high-density lipoprotein-cholesterol (TG:HDL-C) (26). Although it appears to be well tolerated and potentially beneficial in improving cholesterol metabolism, pantethine is not a vitamin, and the decision to use pharmacologic doses of pantethine to treat elevated blood cholesterol or triglycerides should only be made in collaboration with a qualified health care provider who provides appropriate follow up.

Figure 5. Chemical Structures of Some Pantothenic Acid Derivatives



Graying of hair

Mice that are deficient in pantothenic acid developed skin irritation and graying of the fur, which is reversed by pantothenic acid administration. In humans, there is no evidence that taking pantothenic acid as supplements or using shampoos containing pantothenic acid can prevent or restore hair color.

Sources

Food sources

Pantothenic acid is available in a variety of foods, usually as a component of coenzyme A (CoA) and 4'-phosphopantetheine (see **Figure 1** above). Upon ingestion, dietary coenzyme A and phosphopantetheine are hydrolyzed to pantothenic acid prior to intestinal absorption (3). Animal liver and kidney, fish, shellfish, pork, chicken, egg yolk, milk, yogurt, legumes, mushrooms, avocados, broccoli, and sweet potatoes are good sources of pantothenic acid. Whole grains are also good sources of pantothenic acid, but processing and refining grains may result in a 35 to 75% loss. Freezing and canning of foods result in similar losses (16). Large national, nutritional surveys failed to estimate pantothenic acid intake, mainly because of the scarcity of data on the pantothenic acid content of food (16). Smaller studies estimated average daily intakes of pantothenic acid to be between 4 and 7 mg/day in adults. **Table 2** lists some rich sources of pantothenic acid, along with their content in milligrams (mg). For more information on the nutrient content of foods, search USDA's FoodData Central.

Table 2. Some Food Sources of Pantothenic Acid

Food	Serving	Pantothenic Acid (mg)
Beef liver (cooked, pan fried)	3 ounces*	5.6
Sunflower seed kernels (dry roasted)	1 ounce	2.0
Fish, trout (mixed species, cooked, dry heat)	3 ounces*	1.9
Yogurt (plain, nonfat)	8 ounces	1.6
Lobster (cooked)	3 ounces	1.4
Avocado (raw, California)	½ fruit	1.0
Sweet potato (cooked, with skin)	1 medium (½ cup)	1.0
Milk	1 cup (8 fluid ounces)	0.87
Pork (tenderloin, lean, cooked, roasted)	3 ounces*	0.86
Chicken (light meat, cooked, roasted)	3 ounces*	0.83
Egg (cooked, hard-boiled)	1 large	0.70
Cheese, feta	½ cup (crumbled)	0.70
Lentils (mature seeds, cooked, boiled)	½ cup	0.63
Split peas (mature seeds, cooked, boiled)	½ cup	0.58
Mushrooms (white, raw)	½ cup (chopped)	0.52
Peanuts	1 ounce	0.50
Broccoli (cooked, boiled)	½ cup (chopped)	0.48
Orange	1 whole	0.30
Whole-wheat bread	1 slice	0.21
*A three-ounce serving of meat or fish is about the size of a deck of cards.		

Intestinal bacteria

The bacteria that normally colonize the colon (large intestine) are capable of synthesizing pantothenic acid. A specialized transporter for the uptake of biotin and pantothenic acid was identified in cultured cells derived from the lining of the colon, suggesting that humans may be able to absorb pantothenic acid and biotin produced by intestinal bacteria (27). However, the extent to which bacterial synthesis contributes to pantothenic acid intake in humans is not known (28).

Supplements

Pantothenol and pantothenate

Supplements commonly contain pantothenol (panthenol), a stable alcohol analog of pantothenic acid, which can be rapidly converted to pantothenic acid by humans. Calcium and sodium D-pantothenate, the calcium and sodium salts of pantothenic acid, are also available as supplements.

Pantethine

Pantethine is used as a cholesterol-lowering agent in Japan and is available in the US as a dietary supplement (29).

Safety

Toxicity

Pantothenic acid is not known to be toxic in humans. The only adverse effect noted was diarrhea resulting from very high intakes of 10 to 20 g/day of calcium D-pantothenate (30). However, there is one case report of life-threatening eosinophilic pleuropericardial effusion in an elderly woman who took a combination of 10 mg/day of biotin and 300 mg/day of pantothenic acid for two months (31). Due to the lack of reports of adverse effects when the Dietary Reference Intakes (DRI) for pantothenic acid were established in 1998, the Food and Nutrition Board of the Institute of Medicine did not establish a tolerable upper intake level (UL) for pantothenic acid (16). Pantethine is generally well tolerated in doses up to 1,200 mg/day. However, gastrointestinal side effects, such as nausea and heartburn, have been reported (29). Also, topical formulations containing up to 5% of dexpanthenol (D-panthenol) have been safely used for up to one month. Yet, a few cases of skin irritation, contact dermatitis, and eczema have been reported with the use of dexpanthenol-containing ointments (32, 33).

Nutrient interactions

Large doses of pantothenic acid have the potential to compete with biotin for intestinal and cellular uptake by the human sodium-dependent multivitamin transporter (hSMVT) (27, 34).

Drug interactions

Oral contraceptives (birth control pills) containing estrogen and progestin may increase the requirement for pantothenic acid (30). Use of pantethine in combination with cholesterol-lowering drugs called statins (HMG-CoA reductase inhibitors) or with nicotinic acid (see the article on Niacin) may produce additive effects on blood lipids (29).

Linus Pauling Institute Recommendation

More data are needed to define the amount of dietary pantothenic acid required to promote optimal health or prevent chronic disease. The Linus Pauling Institute supports the recommendation by the Food and Nutrition Board of 5 mg/day of pantothenic acid for adults. A varied diet should provide enough pantothenic acid for most people. Following the Linus Pauling Institute recommendation to take a daily multivitamin/mineral supplement that contains 100% of the Daily Value (DV) for pantothenic acid will ensure an intake of at least 5 mg/day.

Older adults (>50 years)

There is currently little evidence that older adults differ in their intake of or their requirement for pantothenic acid. Most multivitamin/mineral supplements provide at least 5 mg/day of pantothenic acid.

Summary

- Riboflavin is the precursor of the coenzymes flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN). FAD and FMN act as electron carriers in a number of oxidation-reduction (redox) reactions involved in energy production, cellular antioxidant function, and in numerous metabolic pathways. *(More information)*
- Riboflavin (as FAD or FMN) is required for the metabolism of iron and vitamin B_6, and in the synthesis of niacin from tryptophan. It also plays an essential role in folate and related one-carbon metabolism, where FAD is required as a cofactor for methylenetetrahydrofolate reductase (MTHFR), a key folate-metabolizing enzyme. *(More information)*
- Clinical signs of riboflavin deficiency include skin disorders, angular stomatitis, cheilosis, glossitis, and corneal vascularization. Riboflavin deficiency occurs commonly in low- and middle-income countries. *(More information)*
- Subclinical deficiency (low status) of riboflavin without clinical signs may be widespread, including in high-income countries, but it usually goes undetected because riboflavin biomarkers are very rarely measured in human studies. *(More information)*
- Low riboflavin status is associated with preeclampsia in pregnant women, a condition that may progress to eclampsia and cause severe bleeding and death *(More information)*. It is also linked with cataracts in older individuals. *(More information)*
- Deficient/low status of riboflavin interferes with the metabolism of folate, particularly in individuals with the variant 677TT genotype in *MTHFR*. There is some evidence that these individuals exhibit a higher risk of cancer. *(More information)*
- Case reports have shown that patients with autosomal recessive disorders of riboflavin metabolism may benefit from riboflavin supplementation. *(More information)*
- The *MTHFR* C677T polymorphism is associated with an increased risk of hypertension. Intervention studies have shown that supplementation with riboflavin (the MTHFR cofactor) effectively lowers blood pressure, specifically in individuals with the variant *MTHFR* 677TT genotype. *(More information)*
- Riboflavin supplementation has been evaluated as a prophylactic agent for migraine headache, but the results are conflicting. *(More information)*
- Riboflavin supplementation has been studied as a potential adjunct therapy in cancer, certain eye disorders, and multiple sclerosis. *(More information)*

Riboflavin is a water-soluble B vitamin, also known as vitamin B_2. Riboflavin is primarily found as an integral component of the coenzymes flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN) (1). Coenzymes derived from riboflavin are termed flavocoenzymes, and enzymes that use a flavocoenzyme are called flavoproteins (2).

Function

Oxidation-reduction (redox) reactions

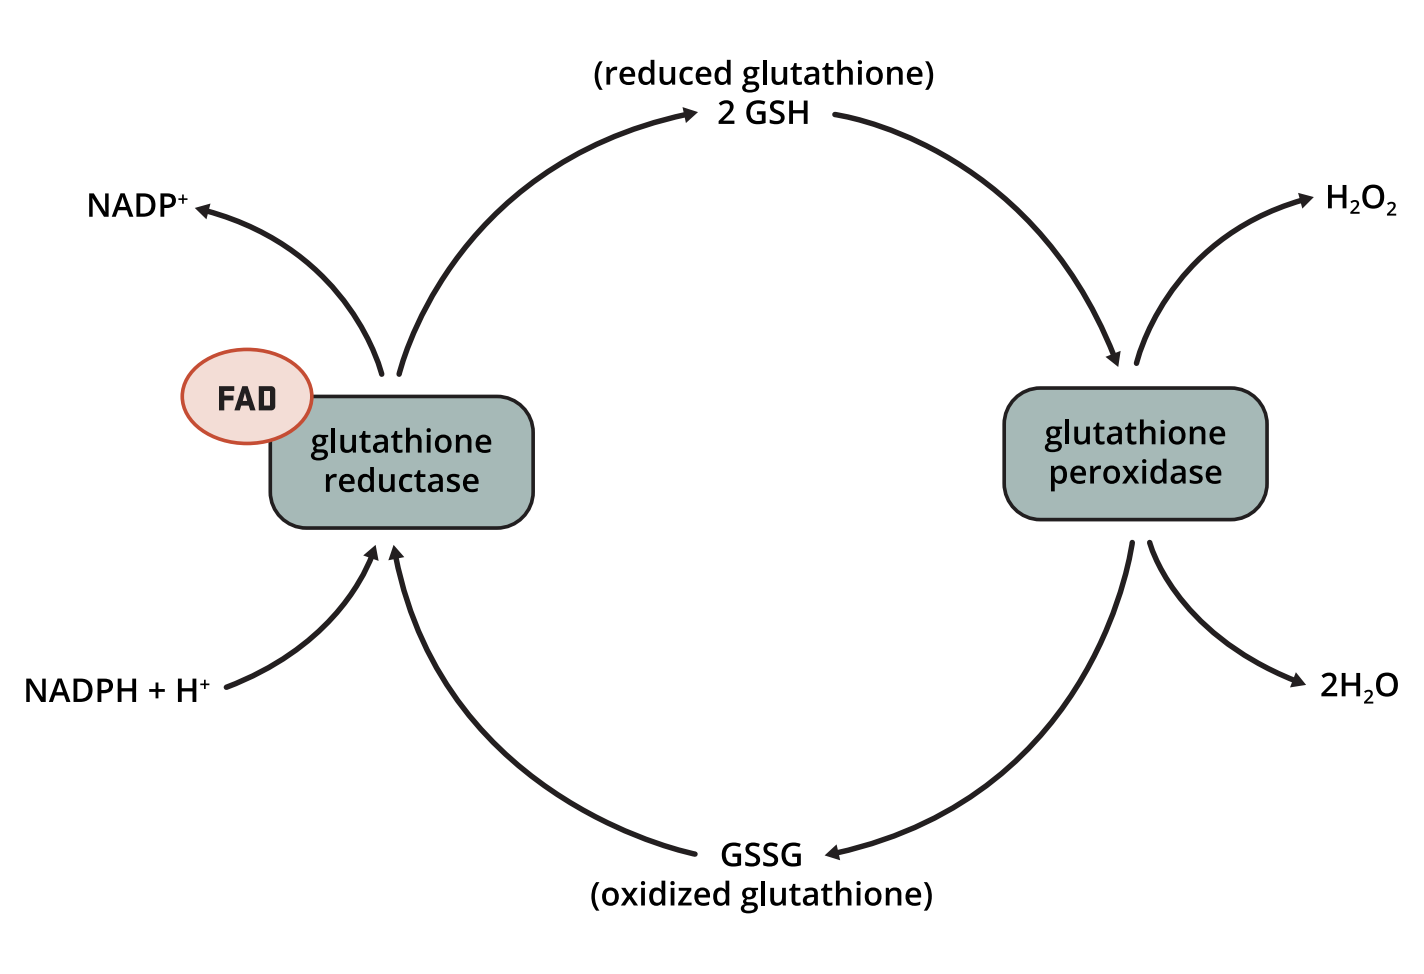
Living organisms derive most of their energy from redox reactions, which are processes that involve the transfer of electrons. Flavocoenzymes participate in redox reactions in numerous metabolic pathways (3). They are critical for the metabolism of carbohydrates, lipids, and proteins. FAD is part of the electron transport (respiratory) chain, which is central to energy production. In conjunction with cytochrome P-450, flavocoenzymes also participate in the metabolism of drugs and toxins (4).

Antioxidant functions

Glutathione reductase is a FAD-dependent enzyme that participates in the redox cycle of glutathione. The glutathione redox cycle plays a major role in protecting organisms from reactive oxygen species, such as hydroperoxides. Glutathione reductase requires FAD to regenerate two molecules of reduced glutathione from oxidized glutathione. Riboflavin deficiency has been associated with increased oxidative stress (4) Measurement of glutathione reductase activity in red blood cells is commonly used to assess riboflavin nutritional status (5).

Glutathione peroxidases (GPx), selenium-containing enzymes, require two molecules of reduced glutathione to break down hydroperoxides. GPx are involved in the glutathione oxidation-reduction (redox) cycle (**Figure 1**).

Figure 1. Glutathione Oxidation-Reduction (Redox) Cycle



FAD - flavin adenine dinucleotide (one of the two cofactor forms of riboflavin)

One molecule of hydrogen peroxide is reduced to two molecules of water, while two molecules of glutathione (GSH) are oxidized in a reaction catalyzed by the selenoenzyme, glutathione peroxidase. Oxidized glutathione (GSSG) may be reduced by the flavin adenine dinucleotide (FAD)-dependent enzyme, glutathione reductase.

Xanthine oxidase, another FAD-dependent enzyme, catalyzes the oxidation of hypoxanthine and xanthine to uric acid. Uric acid is one of the most effective water-soluble antioxidants in the blood. Riboflavin deficiency can result in decreased xanthine oxidase activity, reducing blood uric acid levels (6).

Nutrient interactions

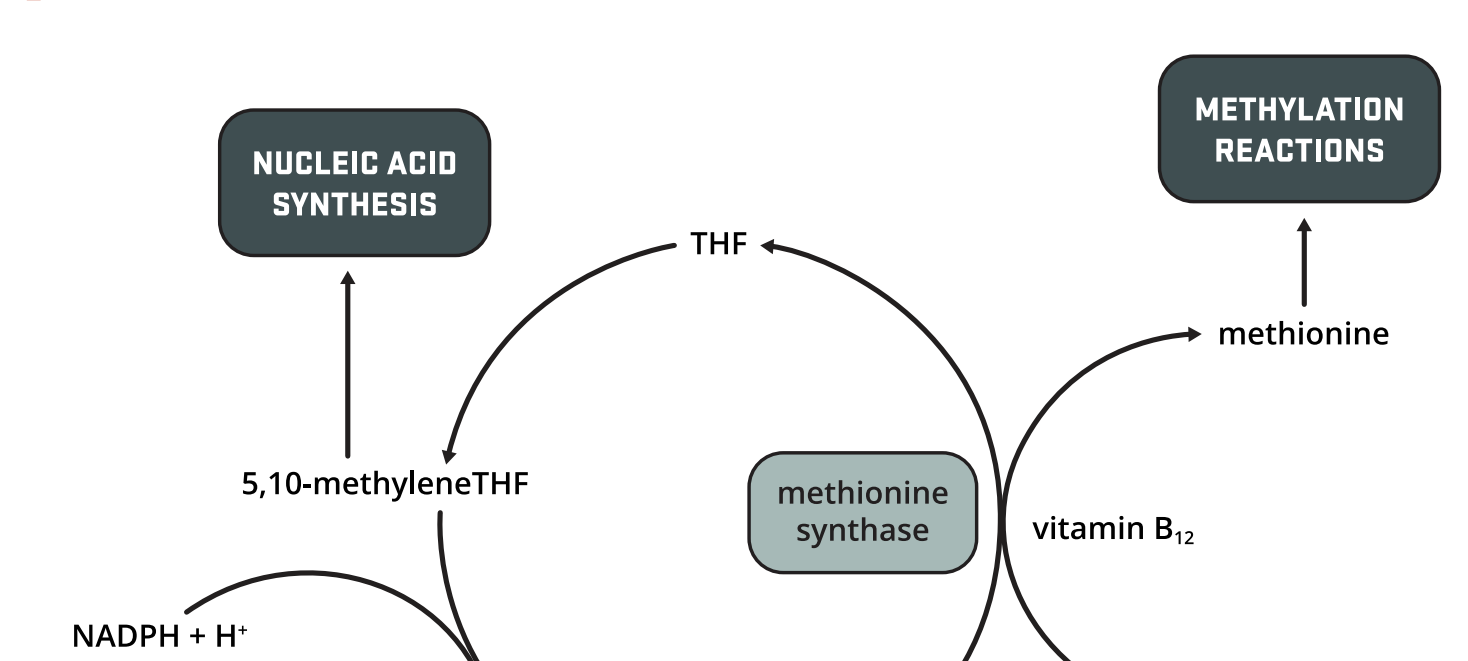
Riboflavin (as FAD or FMN) is required for the synthesis of niacin from tryptophan, and in the metabolism of vitamin B_6 and iron. It is also essential for folate and related one-carbon metabolism, where FAD is required as a cofactor for methylenetetrahydrofolate reductase (MTHFR), a key folate-metabolizing enzyme.

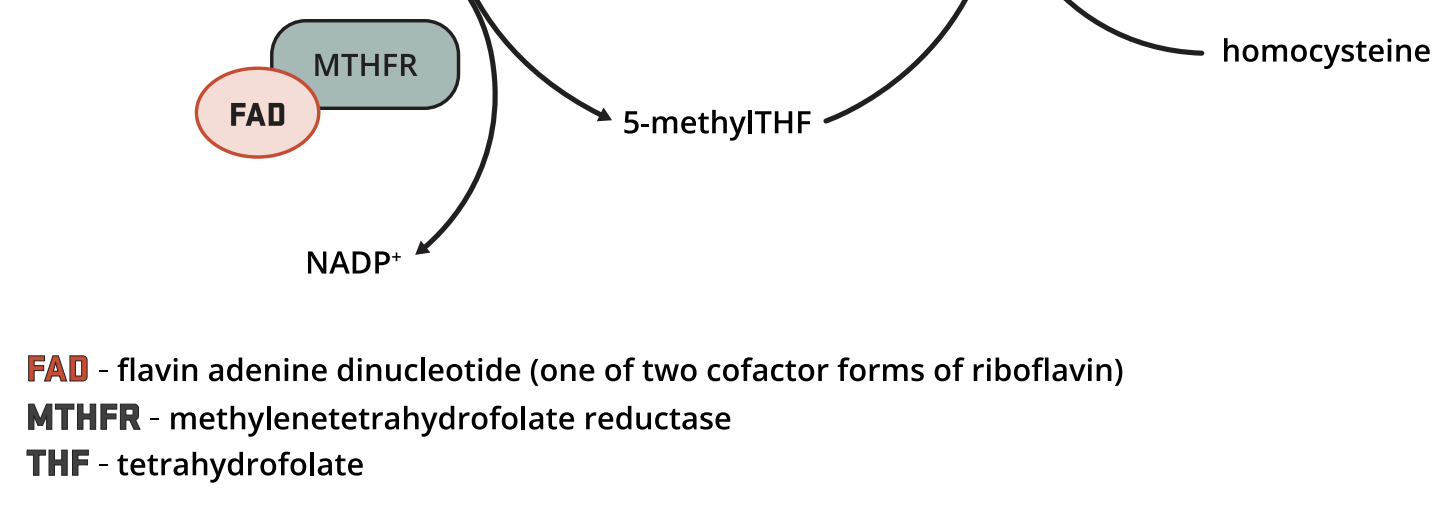
B-complex vitamins

Flavoproteins are involved in the metabolism of several other vitamins: vitamin B_6, niacin, vitamin B_{12}, and folate. Therefore, low and deficient riboflavin status can affect several enzyme systems. The conversion of vitamin B_6 to its active coenzyme form in tissues, pyridoxal 5'-phosphate (PLP), requires the FMN-dependent enzyme, pyridoxine 5'-phosphate oxidase (PPO) (7). Human studies have provided evidence of the metabolic dependency of vitamin B_6 on riboflavin status in older (8-10) and younger (10) adults. The synthesis of the niacin-containing coenzymes, NAD and NADP, from the amino acid tryptophan, requires the FAD-dependent enzyme, kynurenine 3-monooxygenase. Severe riboflavin deficiency can thus decrease the conversion of tryptophan to NAD and NADP, increasing the risk of niacin deficiency (3).

Methylenetetrahydrofolate reductase (MTHFR) is an FAD-dependent enzyme that plays a key role in one-carbon metabolism by catalyzing the reduction of 5,10 methyleneTHF to 5 methylTHF. Once formed, 5 methylTHF is used by methionine synthase for the vitamin B_{12}-dependent conversion of homocysteine to methionine and the formation of THF (**Figure 2**). Both FMN and FAD are coenzymes for the enzyme methionine synthase reductase, which is responsible for the regeneration of methylcobalamin, the biologically active form of vitamin B_{12} acting as a coenzyme for methionine synthase (11). Along with other B vitamins (folate, vitamin B_{12}, and vitamin B_6), higher dietary riboflavin intakes have been associated with lower plasma concentrations of homocysteine (12). In individuals homozygous for the C677T polymorphism in the *MTHFR* gene, low riboflavin status is associated with elevated plasma homocysteine, and in turn linked with a higher risk of cardiovascular disease and other chronic diseases (13, 14). Furthermore, supplementation with riboflavin results in marked lowering of homocysteine concentrations specifically in individuals with the variant *MTHFR* 677TT genotype (15). Such results illustrate that chronic disease risk may be influenced by complex interactions between genetic and dietary factors.

Figure 2. Folate and Nucleic Acid Metabolism





homocysteine
MTHFR
FAD
5-methylTHF
NADP⁺
FAD - flavin adenine dinucleotide (one of two cofactor forms of riboflavin)
MTHFR - methylenetetrahydrofolate reductase
THF - tetrahydrofolate

5,10-methyleneTHF is required for the synthesis of nucleic acids, and 5-methylTHF is required for the formation of methionine from homocysteine. Methionine, in the form of S-adenosylmethionine, is required for many methylation reactions, including DNA methylation. MTHFR is a flavin-dependent enzyme required to catalyze the reduction of 5,10-methyleneTHF to 5-methylTHF.

Iron

Riboflavin deficiency alters iron metabolism. Although the mechanism is not clear, research in animals suggests that riboflavin deficiency may impair iron absorption, increase intestinal loss of iron, and/or impair iron utilization for the synthesis of hemoglobin (16). In humans, low dietary intake of riboflavin has been associated with an increased risk for anemia (17), and improving riboflavin nutritional status has been found to increase circulating hemoglobin levels (18). Correction of riboflavin deficiency in individuals who are both riboflavin and iron deficient improves the response of iron-deficiency anemia to iron therapy (19). Anemia during pregnancy, a worldwide public health problem, is responsible for considerable perinatal morbidity and mortality (20, 21). The management of maternal anemia typically involves supplementation with iron alone or iron in combination with folic acid (22). It is possible that the inclusion of riboflavin could enhance the effects of iron-folic acid supplementation in treating maternal anemia, but the evidence is limited. There are, however, randomized, double-blind intervention trials conducted in pregnant women with anemia in Southeast Asia showing that a combination of folic acid, iron, vitamin A, and riboflavin improved hemoglobin levels and decreased anemia prevalence compared to iron-folic acid supplementation alone (23, 24).

Deficiency

Ariboflavinosis is the medical name for clinical riboflavin deficiency, which occurs commonly in low- and middle-income countries. Riboflavin deficiency is rarely found in isolation; it typically occurs in combination with deficiencies of other water-soluble vitamins. Clinical signs of riboflavin deficiency include sore throat, redness and swelling of the lining of the mouth and throat, cracks or sores on the outsides of the lips (cheliosis) and at the corners of the mouth (angular stomatitis), inflammation and redness of the tongue (magenta tongue), and a moist, scaly skin inflammation (seborrheic dermatitis). Other signs may involve the formation of blood vessels in the clear covering of the eye (vascularization of the cornea) and decreased red blood cell count in which the existing red blood cells contain normal levels of hemoglobin and are of normal size (normochromic normocytic anemia) (1, 3). Subclinical deficiency (low status) of riboflavin without clinical signs may be widespread, including in high-income countries, but usually goes undetected because riboflavin biomarkers are very rarely measured in human studies. Low or deficient riboflavin status may result in decreased conversion of vitamin B$_6$ to its active coenzyme form (PLP) and decreased conversion of tryptophan to niacin (see Nutrient interactions).

Preeclampsia is defined as the presence of elevated blood pressure, protein in the urine, and edema (significant swelling) during pregnancy. About 5% of women with preeclampsia progress to eclampsia, a significant cause of maternal and fetal death. Eclampsia is characterized by seizures, in addition to high blood pressure and increased risk of hemorrhage (severe bleeding) (25). A study in 154 pregnant women at increased risk of preeclampsia found that those who were riboflavin deficient were 4.7 times more likely to develop preeclampsia than those who had adequate riboflavin nutritional status (26). The cause of preeclampsia-eclampsia is not known. Decreased intracellular levels of flavocoenzymes could cause mitochondrial dysfunction, increase oxidative stress, and interfere with nitric oxide release and thus blood vessel dilation – all of these changes have been associated with preeclampsia (26).

A 2015 meta-analysis of 54 case-control studies found that the *MTHFR* C677T polymorphism was associated with an increased risk of preeclampsia, especially in Caucasian and Asian populations (27). The reduction in the flavoprotein MTHFR activity observed in individuals with the variant *MTHFR* 677TT genotype leads to an increase in plasma homocysteine (14); higher homocysteine concentrations have been associated with preeclampsia (28). One small randomized controlled trial in 450 pregnant women in West Africa, without specified *MTHFR* genotype but at high risk for preeclampsia, found that supplementation with 15 mg of riboflavin daily was not effective in preventing the condition (29), but the study was likely underpowered to detect a significant effect. Further studies are needed to assess the potential benefit of riboflavin supplementation in reducing perinatal complications generally and specifically in preeclamptic women with the *MTHFR* 677TT genotype.

Risk factors for riboflavin deficiency

Alcoholics are at an increased risk of riboflavin deficiency, likely due to decreased dietary intake, decreased absorption, and/or impaired utilization of riboflavin. Interestingly, the elevated blood homocysteine concentrations associated with riboflavin deficiency rapidly decline during alcohol withdrawal (30). Additionally, people with anorexia rarely consume adequate dietary riboflavin, and those who are lactose intolerant are unlikely to meet requirements due to the avoidance of dairy products, the major dietary sources of riboflavin. The conversion of riboflavin into the active cofactor forms FAD and FMN is impaired in hypothyroidism and adrenal insufficiency (3, 4). Further, people who are very active physically (athletes, laborers) may have slightly increased riboflavin requirements. However, riboflavin supplementation has not generally been found to increase exercise tolerance or performance (31) unless the individuals are riboflavin deficient (32).

The Recommended Dietary Allowance (RDA)

The RDA for riboflavin, revised in 1998, is based on the prevention of deficiency (**Table 1**). Clinical signs of deficiency in humans appear at intakes of less than 0.5 to 0.6 milligrams (mg)/day, and urinary excretion of riboflavin is seen at intake levels of approximately 1 mg/day (1).

Table 1. Recommended Dietary Allowance (RDA) for Riboflavin

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	0.3 (AI)	0.3 (AI)
Infants	7-12 months	0.4 (AI)	0.4 (AI)
Children	1-3 years	0.5	0.5
Children	4-8 years	0.6	0.6
Children	9-13 years	0.9	0.9
Adolescents	14-18 years	1.3	1.0
Adults	19 years and older	1.3	1.1
Pregnancy	all ages	-	1.4
Breast-feeding	all ages	-	1.6

Disease Prevention

Cataracts

Age-related cataracts are the leading cause of visual disability in the US and other developed countries. Research has focused on the role of nutritional antioxidants because of evidence that light-induced oxidative damage of lens proteins may lead to the development of age-related cataracts. A case-control study found significantly decreased risk of age-related cataracts (33% to 51%) in men and women in the highest quintile of dietary riboflavin intake (median of 1.6 to 2.2 mg/day) compared to those in the lowest quintile (median of 0.08 mg/day in both men and women) (33). Another case-control study reported that individuals in the highest quintile of riboflavin status, as measured by red blood cell glutathione reductase activity, had approximately one-half the occurrence of age-related cataract as those in the lowest quintile of riboflavin status, though the results were not statistically significant (34). A cross-sectional study of 2,900 Australian men and women, 49 years of age and older, found that those in the highest quintile of riboflavin intake were 50% less likely to have cataracts than those in the lowest quintile (35). A prospective cohort study of more than 50,000 women did not observe a difference between rates of cataract extraction between women in the highest quintile of riboflavin intake (median of 1.5 mg/day) and women in the lowest quintile (median of 1.2 mg/day) (36). However, the range between the highest and lowest quintiles was small, and median intake levels for both quintiles were above the RDA for riboflavin. A study in 408 women found that higher dietary intakes of riboflavin were inversely associated with a five-year change in lens opacification (37). A randomized controlled trial using a fractional factorial design showed that compared with placebo, the combined supplementation with riboflavin (3 mg/day) and niacin (40 mg/day) for five to six years reduced the prevalence of nuclear cataract but increased the progression of posterior subcapsular cataracts in population affected by multiple nutrient deficiency living in rural China (38). Of note is that the results of this trial are somewhat conflicting, and the study design does not allow the effects of riboflavin and niacin to be differentiated. In summary, there is some evidence predominantly from observational studies, that suggests higher riboflavin status might be beneficial; however, more evidence from well-designed, randomized controlled trials is needed to confirm a role for riboflavin in the prevention of cataracts.

Cancer

The flavoprotein, methylenetetrahydrofolate reductase (MTHFR), plays a pivotal role in folate-mediated one-carbon metabolism. MTHFR converts 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, the cofactor form necessary for the re-methylation of homocysteine to methionine (see **Figure 2** above). The conversion of homocysteine to methionine is of importance for homocysteine detoxification and for the production of S-adenosylmethionine (SAM), the methyl donor for the methylation of DNA and histones. Folate deficiency and elevated homocysteine concentrations may increase cancer risk (see the article on Folate). Aberrant methylation changes are also known to alter the structure and function of DNA and histones during cancer development (39). Since MTHFR controls the detoxification of homocysteine and the supply of methyl groups for SAM synthesis, a reduction in its activity can affect homocysteine metabolism and disturb cellular methylation processes. The substitution of a cytosine by a thymine in position 677 (c.677C>T) in the *MTHFR* gene is a polymorphism that affects the binding of FAD and leads to an increased propensity for MTHFR to lose its flavin coenzyme (40). Subjects homozygous for this mutation (*MTHFR* 677TT genotype) exhibit reduced MTHFR activity and increased risk for a wide variety of cancers (41-43), but the evidence of an association between this polymorphism and cancer is inconsistent, with some reports suggesting a reduction in colorectal cancer risk with the T allele (44).

As mentioned above (see B-complex vitamins), riboflavin intake is a determinant of homocysteine concentration. This suggests that riboflavin status can influence MTHFR activity and the metabolism of folate, thereby affecting cancer risk (43). In a randomized, double-blind, placebo-controlled study, 93 subjects with colorectal polyps and 86 healthy subjects were given a placebo, folic acid (400 or 1,200 μg/day), or folic acid (400 μg/day) plus riboflavin (5 mg/day) for 45 days. These interventions significantly improved folate and riboflavin status in vitamin-supplemented individuals compared to those taking the placebo. Interestingly, riboflavin enhanced the effect of 400 μg folic acid on circulating 5-methyltetrahydrofolate (5-MTHF) specifically in the polyp patients with the C677T genetic variant (45). This suggests that riboflavin may improve the response to folic acid supplementation in individuals with a reduced MTHFR activity. Additionally, a prospective cohort study of 88,045 postmenopausal women found total (dietary plus supplemental) intake of riboflavin to be inversely correlated with colorectal cancer risk when comparing the highest (>3.97 mg) and lowest (<1.80 mg) quartiles of daily intake (46); intake in the reference group was well above the RDA for riboflavin of 1.1 mg/day. The subjects in this study were not prescreened to identify those with the variant *MTHFR* 677TT genotype, and the association between this polymorphism and colorectal cancer remains unclear, with some reports suggesting a reduction in cancer risk with the T allele (44). Two meta-analyses have found inverse associations between riboflavin intake and risk of colorectal cancer (47, 48). The most recent of these was a dose-response meta-analysis that pooled results from five prospective cohort studies, nine case-control studies, and two studies reporting blood concentrations of riboflavin. This analysis found that higher intakes of riboflavin were associated with a significantly lower risk of colorectal cancer (RR=0.87; 95% CI, 0.81-0.93); inverse associations were observed for both dietary riboflavin intake and total daily intake from the diet and supplements (48).

Associations between riboflavin intake and cancer risk have also been evaluated in other types of cancer. A seven-year intervention study evaluated the use of riboflavin-fortified salt in 22,093 individuals at high risk for esophageal cancer in China. Riboflavin status and esophageal pathology (percent normal, dysplastic, and cancerous tissues) improved in the intervention group compared to the control group, but the lower incidence of esophageal cancer found in the intervention group was not statistically significant (49). Additionally, a 25-year follow up of an intervention trial in patients at high risk for gastric cancer found that dietary supplementation with riboflavin (3.2 mg/day) and niacin (40 mg/day) for five years decreased the risk of mortality from esophageal cancer by 8% but had no effect on mortality from gastric cancer (50). In the Melbourne Collaborative Cohort Study, which followed 41,514 men and women over a 15-year period, weak inverse associations were found between riboflavin intake and lung cancer (51) and breast cancer (52); no association of riboflavin intake with prostate cancer was observed in this cohort (53). A 2017 meta-analysis of 10 observational studies found an overall inverse association of riboflavin intake and breast cancer incidence and reported a 6% lower risk with each 1 mg/day increment of riboflavin intake (54). Further, studies to date have not found riboflavin intake or measures of riboflavin status to be associated with renal cell carcinoma, as reviewed in a recent meta-analysis (55).

Disease Treatment

Migraine headaches

Some evidence indicates that impaired mitochondrial oxygen metabolism in the brain may play a role in the pathology of migraine headaches. Since riboflavin is the precursor of the two flavocoenzymes (FAD and FMN) required by the flavoproteins of the mitochondrial electron transport chain, supplemental riboflavin has been investigated as a treatment for migraine. A randomized controlled trial examined the effect of very high dose riboflavin (400 mg/day) for three months on migraine prevention in 54 men and women with a history of recurrent migraine headaches (56). Riboflavin compared to placebo reduced attack frequency and the number of headache days, though the beneficial effect was most pronounced during the third month of treatment (56). Another study by the same investigators found that treatment with either a β-blocker drug or high-dose riboflavin (400 mg/day) for four months resulted in clinical improvement, but each therapy appeared to act on a distinct pathological mechanism: β-blockers on abnormal cortical information processing and riboflavin on decreased brain mitochondrial energy reserve (57). A small study in 23 patients reported a reduction in median migraine attack frequency after supplementation with 400 mg of riboflavin daily for three months (58). A single-blinded, randomized, parallel group trial in 85 patients with migraine headaches (ages 15-55 years), high-dose riboflavin supplementation (400 mg/day) for 12 weeks decreased migraine frequency, duration, and severity compared to baseline and was as effective as sodium valproate (500 mg/day) (59), a medication with established efficacy in migraine preventative therapy (60). Riboflavin elicited significantly fewer adverse effects compared to the drug (59). Thus, although the available trials have been small and short term, most studies to date suggest that high-dose riboflavin supplementation might be a useful adjunct therapy in adults with migraine headaches.

A few randomized controlled trials have investigated the effect of riboflavin supplementation on the frequency and severity of headache attacks in children with migraines. An initial study evaluated riboflavin at 200 mg/day for 12 weeks in 48 children of ages 5 to 15 years old (61). A second study was a cross-over trial with half of the 42 children, ages 6 to 13, receiving 50 mg/day riboflavin for 16 weeks then placebo (100 mg/day carotene) for 16 weeks (with a four-week washout period in between each), while the other half were first given the placebo then riboflavin (62). Neither study showed differences in the frequency, duration, or intensity of migraines between treatments. However, a more recent trial found a benefit of intervention with higher dose riboflavin: children with migraine treated with 400 mg/day of riboflavin for 12 weeks (n=30) had reductions in migraine frequency and duration, but not intensity, compared to placebo (n=30), yet no benefit was seen in children taking 200 mg/day for 12 weeks in this study (63). Additionally, a randomized controlled trial in 98 adolescents, ages 12 to 19 years, found that 400 mg/day of riboflavin for three months decreased both headache frequency and duration and improved migraine-related disability compared to placebo (64). Retrospective studies of children and adolescents suffering from migraine have also suggested some benefit associated with supplemental riboflavin (65-67). Thus, studies to date are somewhat conflicting, and more research is needed to understand whether riboflavin supplementation might have utility in the treatment of childhood migraine and the most effective dose required for any beneficial effects.

Metabolic disorders

Increasing evidence from case reports indicates that patients with autosomal recessive disorders caused by defective FAD-dependent enzymes could benefit from riboflavin supplementation.

Multiple acyl-CoA dehydrogenase deficiency (MADD)

MADD, also known as type II glutaric aciduria (or acidemia), is a fatty acid metabolism disorder characterized by the accumulation of short-, medium-, and long-chain acyl-carnitines in various tissues. MADD is classified into three separate types based on age of onset and clinical symptoms: type I MADD is evident in the neonatal period and is characterized by the presence of congenital anomalies; type II MADD is present in the neonatal period but lacks congenital defects; and type III is characterized by late onset, from infancy through adulthood (68), and even as late as the seventh decade of life (69). Clinical symptoms of type I and II MADD present shortly after birth and include hypoglycemia, hyperammonemia, metabolic acidosis, hepatomegaly, and respiratory distress (68, 70); these forms of MADD are often fatal in infancy, even if treated. Type III MADD usually presents later in life and includes milder symptoms, varying from periodic vomiting, rhabdomyolysis, muscle pain and weakness, and exercise intolerance (68, 70). Peripheral neuropathy has also recently been reported as a symptom of adult-onset MADD (71).

MADD is caused by autosomal recessive mutations in genes that impair the activity of enzymes involved in the transfer of electrons from acyl-coenzyme A (acyl-CoA) to coenzyme Q$_{10}$/ubiquinone inside the mitochondria (**Figure 3**). *ETFA*, *ETFB*, and *ETFDH* code for the two subunits of the electron transfer flavoprotein (ETF-A and -B) and for ETF dehydrogenase/ubiquinone oxidoreductase (ETFDH/ETFQO), respectively. Deficiencies in these enzymes (ETF or ETFDH) lead to a decrease in oxidized FAD, which becomes unavailable for FAD-dependent dehydrogenation reactions, including the first step in β-oxidation – a major fatty acid catabolic process that takes place in the mitochondria. A defect in fatty acid β-oxidation causes lipid accumulation in skeletal muscles, leading to lipid storage myopathy characterized by muscle pain and weakness and exercise intolerance.

Together with a low-fat, high-carbohydrate diet, riboflavin supplementation has led to significant clinical improvements in patients with *ETFDH* mutations. The specific type of the mutation in *ETF*/*ETFDH* contributes to age of onset, severity, and responsiveness to riboflavin treatment (70, 72). Additionally, the report of a 20-year-old man with riboflavin-responsive MADD failed to find mutations in *ETF* and *ETFDH* genes, suggesting that other sites of mutation should not be excluded (73). Finally, secondary deficiencies in the respiratory chain are observed in MADD and appear to respond favorably to riboflavin supplementation (72, 74).

ETF - electron transfer flavoprotein
ETF-QO - electron transfer flavoprotein-ubiquinone oxidoreductase system
Q - coenzyme Q₁₀/ubiquinone

Multiple Acyl-CoA Dehydrogenase Deficiency (MADD) is caused by mutations in the genes coding for the ETF and the ETF-QO. These flavoproteins are essential for electron transfer from the fatty acid β-oxidation pathway to the respiratory chain.

Acyl-CoA dehydrogenase 9 deficiency (ACAD9)

Acyl-CoA dehydrogenase family member 9 (ACAD9) is an FAD-dependent enzyme with important roles in both the electron transport chain and β-oxidation of fatty acids in the mitochondria. Recessive mutations in the *ACAD9* gene coding for ACAD9 have been found in patients with mitochondrial complex I deficiency, a respiratory chain disorder (75). Complex I carries electrons from NADH to coenzyme Q$_{10}$ in the electron transport chain. Defective oxidative phosphorylation (ATP synthesis by the respiratory chain) due to complex I deficiency has been linked to a broad variety of clinical manifestations, from neonatal death to late-onset neurodegenerative diseases. The clinical symptoms of complex I deficiency due to *ACAD9* mutations typically include muscle weakness, exercise intolerance, lactic acidosis, and hypertrophic cardiomyopathy (76). However, symptoms can be of varying severity, likely due to the remaining functional activity of ACAD9. For example, affected patients have been reported to exhibit a spectrum of cardiac deficits, including isolated, mild ventricular hypertrophy to severe hypertrophic cardiomyopathy (77).

Riboflavin supplementation (100-300 mg/day) has been shown to increase complex I activity in patients with childhood-onset clinical forms of ACAD9 deficiency. Improvements in muscle strength and exercise tolerance have also been associated with riboflavin supplementation (78-80). A review of cases of ACAD9 deficiency presenting in infancy (i.e., cases with severe symptoms) found riboflavin treatment to be associated with improved survival: 7 of 22 patients treated with riboflavin succumbed to the illness compared to 16 out of 17 untreated patients (76).

Defective riboflavin transport-associated disorders

SLC52A1, *SLC52A2*, and *SLC52A3* genes code for the human riboflavin transporters RFVT1, RFVT2, and RFVT3, respectively. Mutations in these genes lead to riboflavin transporter deficiency, a rare neurodegenerative condition with variable age of onset, from infancy to early stages of adulthood. Autosomal recessive mutations in *SLC52A2* or *SLC52A3* respectively cause disorders known as riboflavin transporter deficiency type 2 (RFVT2 deficiency) and riboflavin transporter deficiency type 3 (RFVT3 deficiency). These genetic disorders were formerly called Brown-Vialetto-Van Laere syndrome and Fazio-Londe syndrome (81). Riboflavin transporter deficiency caused by mutation of *SLC52A1* is exceedingly rare and has been reported in only three cases (reviewed in 82).

Clinical features of riboflavin transporter deficiency can include muscle weakness in the arms and legs, sensory ataxia, bulbar palsy with hypotonia and facial weakness, sensorineural deafness, and respiratory insufficiency (83, 84). High-dose, oral supplementation with riboflavin improves many of these symptoms in the majority of affected patients; such treatment should be given at the time of suspected riboflavin transporter deficiency for a better prognosis (84). A 2016 review of the published literature found that oral supplementation with riboflavin – at doses ranging from 7 to 60 mg/kg/day – led to improved symptoms in 71% of the patients (n=39) and to no deaths (83). In contrast, all of the untreated patients (n=31) had a progression of the disease and a mortality rate of at least 48% (83).

Riboflavin-responsive trimethylaminuria

Primary trimethylaminuria is caused by defective oxidation of trimethylamine by a liver flavoprotein called flavin containing mono-oxygenase 3 (FMO3). Individuals with FMO3 deficiency have increased levels of trimethylamine in urine, sweat, and breath (85). This socially distressing condition is known as "fish odor syndrome" due to the fishy odor and volatile nature of trimethylamine. *FMO3* gene mutations are usually associated with mild or intermittent trimethylaminuria; the condition is sometimes limited to peri-menstrual periods in female subjects or to the consumption of trimethylamine-rich food. The clinical management of the condition includes dietary restriction of trimethylamine and its precursors, such as foods rich in choline and seafood, as well as cruciferous vegetables that contain both trimethylamine precursors and FMO3 antagonists (86). The use of riboflavin supplements was reported in a 17-year-old female patient affected by pyridoxine non-responsive homocystinuria (87). The disease was initially treated with betaine (a choline derivative), which caused body odor secondary to FMO3 deficiency. Riboflavin supplementation (200 mg/day) reduced trimethylamine excretion and the betaine treatment-related body odor. Similar effects were seen with riboflavin supplementation in two pediatric patients (88). The data suggest that riboflavin might help maximize residual FMO3 enzyme activity in patients with primary trimethylaminuria. Moreover, a recent case report in a 35-year-old male with HIV described supplemental riboflavin as an effective treatment for secondary trimethylaminuria caused by antiretroviral therapy (89).

Hypertension

Hypertension in adulthood is recognized as the leading risk factor contributing to mortality worldwide primarily from cardiovascular disease, while hypertension in pregnancy leads to serious adverse fetal and maternal outcomes. A number of risk factors are recognized to contribute to the development of hypertension. In recent years, evidence has emerged from genetic and clinical studies pointing to the role of one-carbon metabolism in blood pressure (90). The common *MTHFR* C677T polymorphism, affecting 1 in 10 adults globally, is associated with higher blood pressure, although this is much less well recognized compared with the phenotype of elevated homocysteine concentrations that was established at the time of discovery of this polymorphism and its link with cardiovascular disease (91). Meta-analyses show that this polymorphism is associated with an increased risk of hypertension by up to 87% and of heart disease and stroke by up to 40% (92). The *MTHFR* C677T polymorphism is also associated with a significantly higher risk of hypertension in pregnancy (93) and with preeclampsia (27).

Since FAD is required as a cofactor for the MTHFR enzyme and the *MTHFR* C677T polymorphism results in decreased MTHFR activity, studies have investigated whether affected individuals may benefit from riboflavin supplementation. In an initial randomized controlled trial in 77 healthy young adults stratified by *MTHFR* genotype, riboflavin supplementation at dietary levels (1.6 mg/day for 12 weeks) resulted in marked lowering of homocysteine concentrations in the *MTHFR* 677TT genotype group, but not in the 677CC or 677CT genotype groups who exhibited normal plasma homocysteine at baseline (15). Three randomized controlled trials subsequently investigated the effect of riboflavin on blood pressure in patients with hypertension with or without overt cardiovascular disease (91, 94, 95). The results of these trials showed that supplementation with low-dose riboflavin (1.6 mg/day for 16 weeks) resulted in significant lowering of blood pressure and reduction in incidence of hypertension specifically in those patients with the variant *MTHFR* 677TT genotype. Riboflavin intervention reduced mean systolic/diastolic blood pressure in those with the TT genotype from 144/87 to 131/80 mm Hg, with no response observed in those without the genetic variant (i.e., the CT or CC genotypes) (89). Notably, the 13 mm Hg decrease in systolic blood pressure occurred even though over 80% of the patients were taking one or more antihypertensive drugs at recruitment, and the addition of supplemental riboflavin was shown to greatly enhance the achievement of goal blood pressure with routine antihypertensive drugs (89, 91). Furthermore, the magnitude of blood pressure response achieved with riboflavin in these trials compares very favorably with typical decreases from other interventions, such as dietary salt reductions of 3 g/day (3.6/1.9 mm Hg) and 6 g/day (7.1/3.9 mm Hg). The trial findings therefore suggest that the excess risk of hypertension linked to this genetic polymorphism can be overcome by low-dose riboflavin supplementation. Also, analysis of plasma samples from individuals participating in these trials showed lower concentrations of S-adenosylmethionine (SAM), an important methyl group donor for methylation reactions, in those with the *MTHFR* 677TT genotype versus the CC genotype (96). However, riboflavin supplementation (1.6 mg/day) for 12 weeks was shown to increase plasma concentrations of SAM and another one-carbon metabolite, cystathionine (96), and thus may have potential in correcting the altered one-carbon metabolism arising with the variant TT genotype.

Thus, studies to date indicate that riboflavin supplementation may have benefits in lowering blood pressure and reducing hypertension in individuals (and sub-populations) affected by the common *MTHFR* C677T polymorphism. However, the mechanisms explaining the blood pressure phenotype and its responsiveness to riboflavin remain unclear. Future studies examining the effects of riboflavin supplementation on one-carbon metabolism may help to elucidate the biological mechanisms involved. Interestingly, a recent randomized controlled trial found that riboflavin supplementation in those with the variant *MTHFR* 677TT genotype resulted in altered DNA methylation of certain genes known to be involved in blood pressure regulation (97).

Cancer

Anticancer agents often display various side effects that may force patients to limit the dose or to discontinue the treatment. The antioxidant effect of co-administering riboflavin (10 mg/day), niacin (50 mg/day), and coenzyme Q$_{10}$ (100 mg/day) was evaluated in 78 postmenopausal patients with breast cancer treated with tamoxifen for 90 days. This supplementation effectively prevented the oxidative stress associated with tamoxifen treatment (98).

Riboflavin can also act as a photosensitizer, and this property may have value in photodynamic therapy of cancer. A mouse model was used to assess the effect of riboflavin in combination with cisplatin, one of the most effective anticancer agents. Under light exposure, riboflavin administration reduced cisplatin-induced DNA damage in the liver and kidneys (99). These results are promising, but human studies are needed to examine whether riboflavin is an effective adjunct to chemotherapy.

Corneal disorders

Corneal ectasia is an eye condition characterized by irregularities of the cornea that affect vision. Corneal cross-linking – a fairly new procedure used by professionals to limit the progression of corneal damage –involves the use of topical riboflavin in conjunction with ultraviolet-A irradiation. Riboflavin functions as a photosensitizer in the reaction. Cross-linking modifies the properties of the cornea and strengthens its architecture (100, 101).

Multiple sclerosis

Multiple sclerosis (MS) is an autoimmune disease of unknown etiology that is characterized by the progressive destruction of myelin and nerve fibers in the central nervous system, causing neurological symptoms in affected individuals (102). Riboflavin appears to have a role in the formation of myelin (103), and oxidative stress has been implicated in the pathogenesis of MS; thus, riboflavin may be helpful in treatment of the disease. A strong inverse association between dietary riboflavin intake and risk for MS was initially observed in a case-control study (104). In a mouse model of MS (i.e., experimental autoimmune encephalomyelitis), riboflavin supplementation improved clinical measures of the disease (105). However, a randomized, double-blind, placebo-controlled pilot study in 29 patients with MS found that supplementation with 10 mg/day of riboflavin for six months had no effect on MS-related disability, assessed by the Expanded Disability Status Scale (106). Large-scale randomized, placebo-controlled trials are needed to determine whether riboflavin supplementation has a beneficial effect in the treatment of MS.

Sources

Food sources

Most plant- and animal-derived foods contain at least small quantities of riboflavin. In the US, wheat flour and bread have been enriched with riboflavin (as well as thiamin, niacin, and iron) since 1943. Data from a US national survey indicate that the average dietary intake of riboflavin is 2.5 mg/day for men and 1.8 mg/day for women (107); these intakes are well above the RDA values of 1.3 mg/day for men and 1.1 mg/day for women. Surveys of adults of ages 70 years or older showed similar intakes: 2.2 mg/day for older men and 1.8 mg day for older women (107).

Riboflavin is heat-stable, but it is easily destroyed upon exposure to light. For instance, up to 50% of the riboflavin in milk contained in a clear glass bottle can be destroyed after two hours of exposure to bright sunlight 6. Nationally representative surveys from the US, Ireland, and the UK showed that milk and other dairy products were the main dietary contributors to riboflavin intake, followed by meat and ready-to-eat breakfast cereals (108-110). Some foods with substantial amounts of riboflavin are listed in **Table 2**, along with their riboflavin content in milligrams (mg). For more information on the nutrient content of food, search USDA's FoodData Central.

The bioavailability of riboflavin from food is reported to be very high, nearly 95% (108). Limited data exist for the relative bioavailability of riboflavin from different food sources, however a cross-over study in healthy women using stable isotopes and kinetic modeling did not find significant differences in riboflavin absorption from milk and spinach (111).

Table 2. Some Food Sources of Riboflavin

Food	Serving	Riboflavin (mg)
Fortified breakfast wheat, puffed cereal	1 cup	0.22
Milk (low-fat, 1%)	1 cup	0.42
Cheddar cheese	1 ounce	0.12
Egg (cooked, hard-boiled)	1 large	0.26
Almonds, unsalted	1 ounce	0.33
Salmon (chinook, cooked)	3 ounces*	0.13
Halibut (greenland, cooked, dry-heat)	3 ounces	0.09
Chicken, light meat (roasted)	3 ounces	0.09
Chicken, dark meat (roasted)	3 ounces	0.16
Beef (ground, cooked)	3 ounces	0.16
Broccoli (boiled, chopped)	½ cup	0.10
Asparagus (boiled)	½ cup	0.13
Spinach (boiled)	½ cup	0.21
Bread, whole-wheat	1 slice	0.05
Bread, white (enriched)	1 slice	0.07
*A three-ounce serving of meat is about the size of a deck of cards.		

Supplements

The most common forms of riboflavin available in supplements are riboflavin and riboflavin 5'-monophosphate. Riboflavin is commonly found in multivitamin and vitamin B-complex preparations (112).

Safety

Toxicity

No toxic or adverse effects of high riboflavin intake in humans are known. Studies in cell culture indicate that excess riboflavin may increase the risk of DNA strand breaks in the presence of chromium (VI), a known carcinogen (113). This may be of concern to workers exposed to chrome, yet no data in humans are available. High-dose riboflavin therapy has been found to intensify urine color to a bright yellow (flavinuria), but this is a harmless side effect. The Food and Nutrition Board did not establish a tolerable upper intake level (UL) when the RDA was revised in 1998 (1).

Drug interactions

Several early reports indicated that women taking high-dose oral contraceptives had diminished riboflavin biomarker status. However, when investigators controlled for dietary riboflavin intake, no differences between users of oral contraceptives and non-users were found (1). Phenothiazine derivatives like the anti-psychotic medication, chlorpromazine (Thorazine), and tricyclic antidepressants inhibit the conversion of riboflavin to FAD and FMN, as do the anti-malarial medication, quinacrine, and the cancer chemotherapy agent, adriamycin (4). Long-term use of the anticonvulsant, phenobarbitol, may increase destruction of riboflavin by liver enzymes, increasing the risk of deficiency (3). Additionally, chronic alcohol consumption has been associated with riboflavin deficiency. In rats chronically fed alcohol, the inhibition of riboflavin transporters caused impairment in intestinal absorption and renal re-uptake of the vitamin (114).

Linus Pauling Institute Recommendation

The RDA for riboflavin (1.3 mg/day for men and 1.1 mg/day for women), which should prevent deficiency in most individuals, is easily met by eating a varied diet. Consuming a varied diet should supply 1.5 mg to 2 mg of riboflavin a day. Following the Linus Pauling Institute recommendation to take a multivitamin/mineral supplement containing 100% of the Daily Values (DV) will ensure an intake of at least 1.3 mg/day of riboflavin.

Older adults (>50 years)

Some experts in nutrition and aging feel that the RDA (1.3 mg/day for men and 1.1 mg/day for women) leaves little margin for error in people over 50 years of age (115, 116). A study of independently living people between 65 and 90 years of age found that almost 25% consumed less than the recommended riboflavin intake, and 10% had biochemical evidence of deficiency (117). Epidemiological studies of cataract prevalence indicate that riboflavin intakes of 1.6 to 2.2 mg/day may reduce the risk of developing age-related cataracts. Additionally, older people suffering from acute ischemic stroke were found to be deficient for riboflavin (118), and riboflavin deficiency has been linked to a higher risk of fracture in postmenopausal women with the *MTHFR* 677T variant (119). Individuals whose diets may not supply adequate riboflavin, especially those over 50 years of age, should consider taking a multivitamin/mineral supplement, which generally provides at least 1.3 mg/day of riboflavin.

Summary

- Thiamin pyrophosphate (TPP), the active form of thiamin, is involved in several enzyme functions associated with the metabolism of carbohydrates, branched-chain amino acids, and fatty acids. *(More information)*
- Severe thiamin deficiency leads to beriberi, a disease that affects multiple organ systems, including the central and peripheral nervous systems. *(More information)*
- Wernicke's encephalopathy refers to an acute neurologic disorder secondary to thiamin deficiency. The Wernicke-Korsakoff syndrome results in persistent alterations in memory formation, along with the encephalopathy-related symptoms. *(More information)*
- Thiamin deficiency can result from poor dietary intake, inadequate provision in parenteral nutrition, reduced gastrointestinal absorption, increased metabolic requirements, or excessive loss of thiamin. Chronic alcohol consumption is the primary cause of thiamin deficiency in industrialized countries. *(More information)*
- Alteration in glucose metabolism has been associated with decreased plasma thiamin concentrations in patients with diabetes. Correction of thiamin deficiency may reduce the risk of vascular complications in these patients. *(More information)*
- Alzheimer's disease has been associated with altered glucose metabolism and thiamin deficiency. Although some promising results have been observed in animal models, it is not known whether supplementation with thiamin or benfotiamine (a synthetic precursor of thiamin) might slow the cognitive decline in patients with Alzheimer's disease. *(More information)*
- A recent study found decreased levels of thiamin in the brain of patients with Huntington's disease. Clinical trials are needed to evaluate whether vitamin supplementation might be a potential therapy. *(More information)*
- Diuretic-induced thiamin excretion may increase the risk of thiamin deficiency and disease severity in subjects with congestive heart failure. Further studies are needed to assess the inclusion of thiamin supplementation in the management of this disease. *(More information)*
- Intravenous thiamin has been studied as potential treatment for sepsis, either as a monotherapy or in combination with other agents like vitamin C and corticosteroids. Large-scale clinical trials are needed to determine its efficacy. *(More information)*

Thiamin (also spelled thiamine) is a water-soluble B vitamin, also known as vitamin B$_1$ or aneurine (1). Isolated and characterized in the 1930s, thiamin was one of the first organic compounds to be recognized as a vitamin (2). Thiamin occurs in the human body as free thiamin and as various phosphorylated forms: thiamin monophosphate (TMP), thiamin triphosphate, adenosine thiamin triphosphate, and thiamin pyrophosphate (TPP), which is also known as thiamin diphosphate.

Function

Coenzyme function

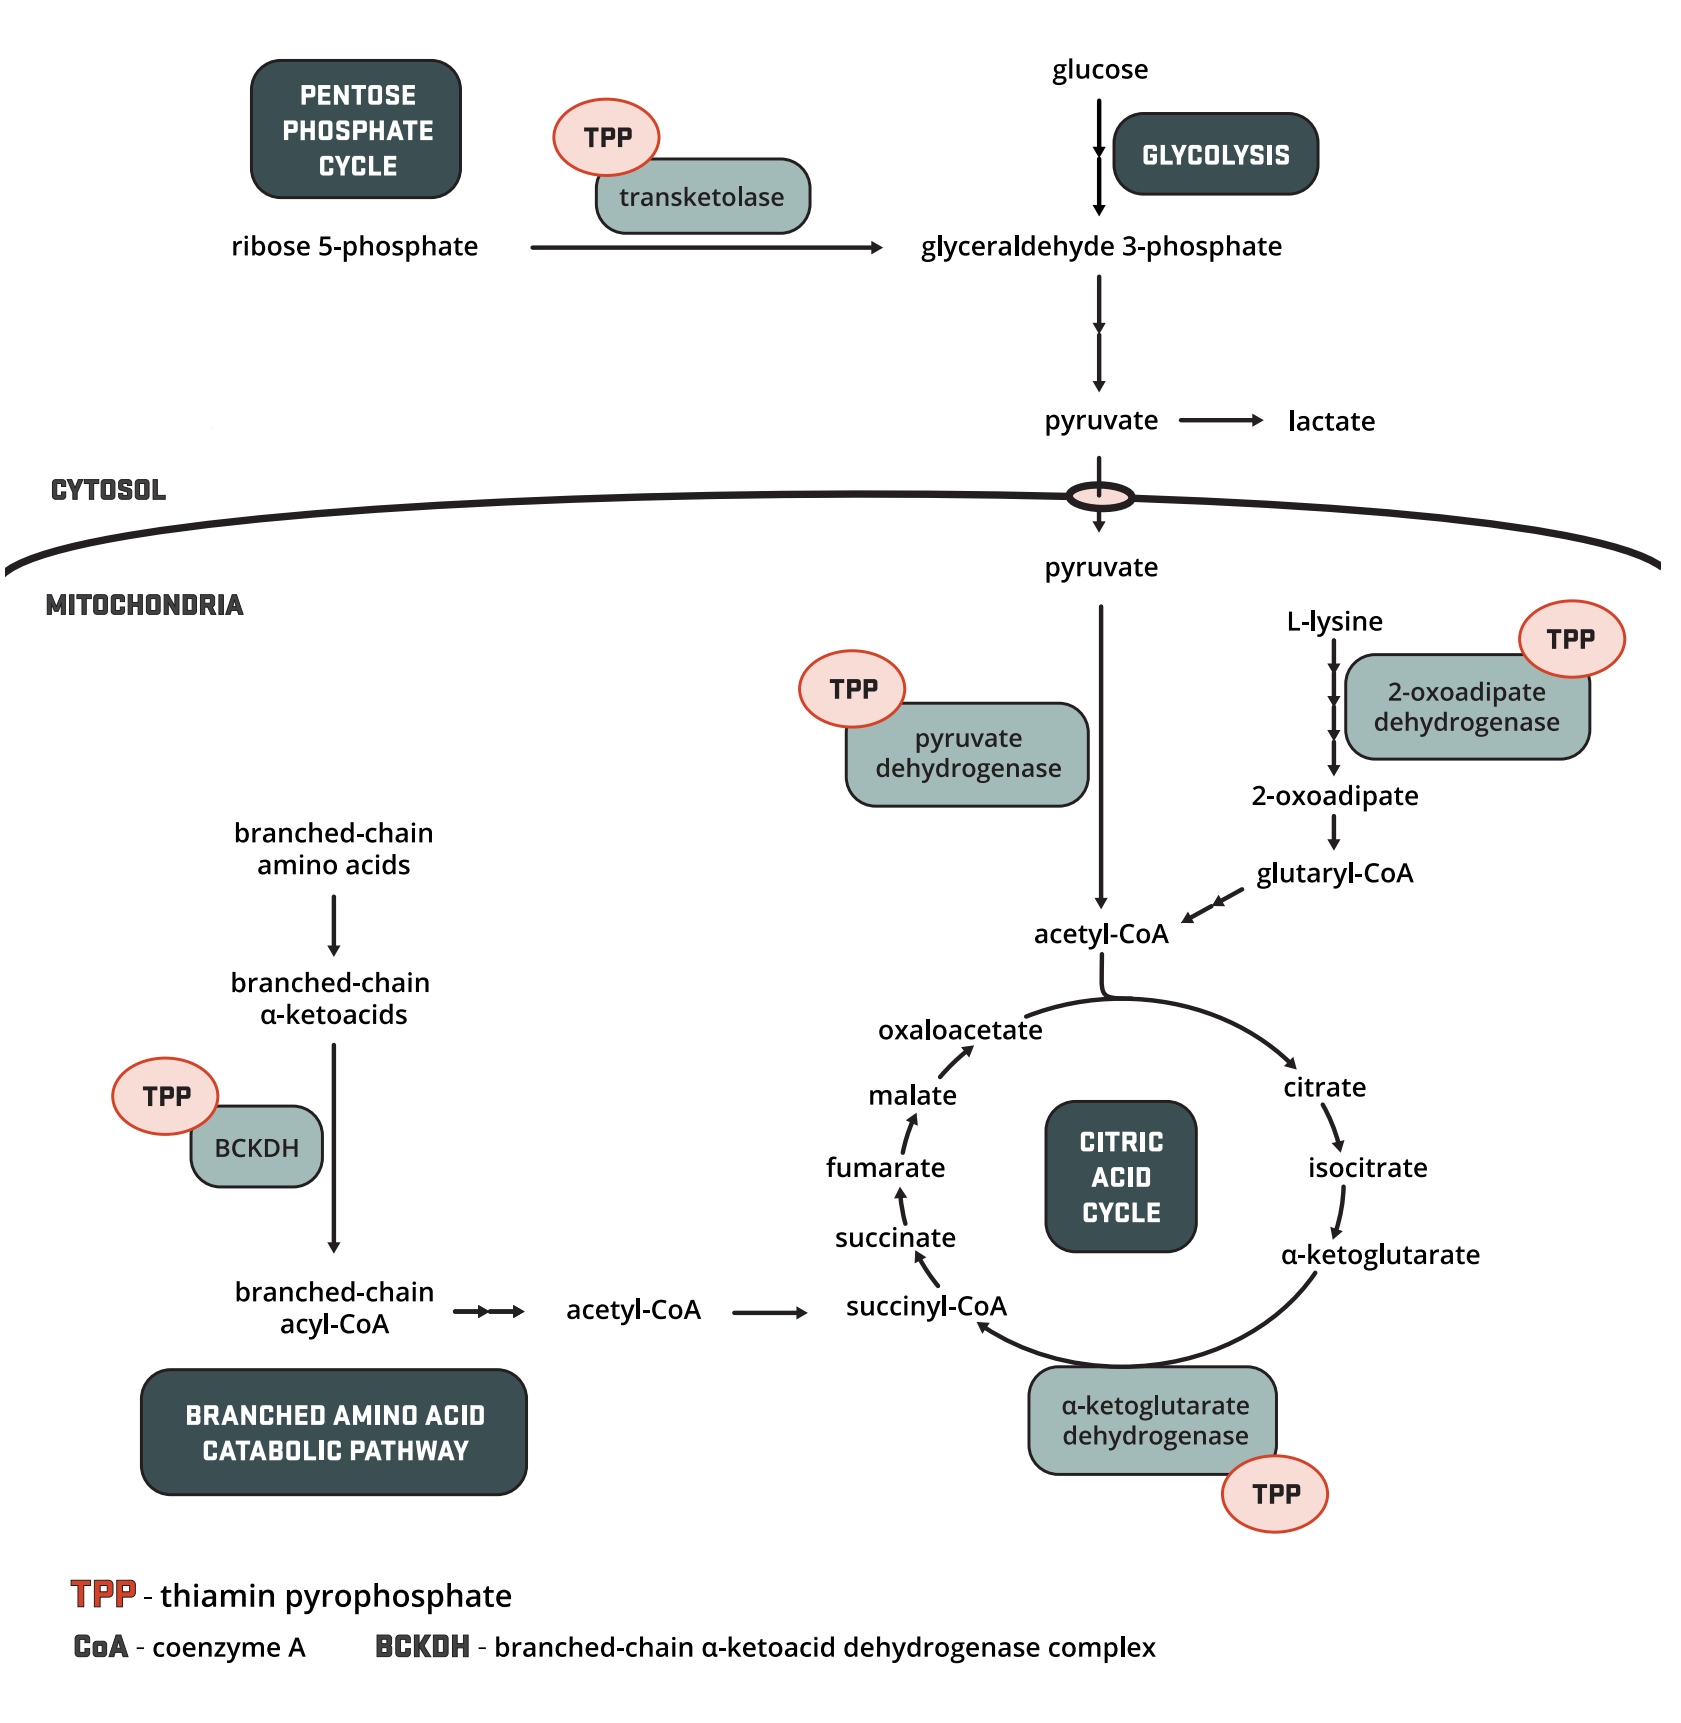
The synthesis of TPP from free thiamin requires magnesium, adenosine triphosphate (ATP), and the enzyme, thiamin pyrophosphokinase. In humans, TPP is required as a coenzyme in the metabolism of carbohydrates and branched-chain amino acids. Forms of thiamin are also needed for ribose synthesis and for α-oxidation of 3-methyl-branched fatty acids.

Pyruvate dehydrogenase, **α-ketoglutarate dehydrogenase**, **2-oxoadipate dehydrogenase**, and **branched-chain α-ketoacid dehydrogenase (BCKDH)** each comprise a different enzyme complex found within cellular organelles called mitochondria. They catalyze the decarboxylation of pyruvate, α-ketoglutarate, 2-oxoadipate, and branched-chain amino acids (BCAA) to form acetyl-coenzyme A (CoA), succinyl-CoA, glutaryl-CoA, and derivatives of BCAA, respectively (**Figure 1**). All products play critical roles in the production of energy from food through their connection to the citric acid (Krebs) cycle (2). BCAA, including leucine, isoleucine, and valine, are eventually degraded into acetyl-CoA and succinyl-CoA to fuel the citric acid cycle. The catabolism of the three BCAAs also contributes to the production of cholesterol and donates nitrogen for the synthesis of the neurotransmitters, glutamate and g-aminobutyric acid (GABA) (3). In addition to the thiamin coenzyme (TPP), each dehydrogenase complex requires a niacin-containing coenzyme (NAD), a riboflavin-containing coenzyme (FAD), and lipoic acid.

Transketolase catalyzes critical reactions in another metabolic pathway occurring in the cytosol, known as the pentose phosphate pathway. One of the most important intermediates of this pathway is ribose-5-phosphate, a phosphorylated 5-carbon sugar required for the synthesis of the high-energy ribonucleotides, such as ATP and guanosine triphosphate (GTP). Nucleotides are the building blocks of nucleic acids, DNA, and RNA. The pentose phosphate pathway also supplies various anabolic pathways, including fatty acid synthesis, with the niacin-containing coenzyme NADPH (1, 4). Because transketolase decreases early in thiamin deficiency and, unlike most thiamin-dependent enzymes, is present in red blood cells, measurement of its activity in red blood cells has been used to assess thiamin nutritional status (2, 5, 6).

2-Hydroxyacyl-CoA lyase is a TPP-dependent enzyme in peroxisomes that catalyzes the catabolism of 3-methyl-branched fatty acids through the process of α-oxidation, the oxidative removal of a single carbon atom from fatty acids like phytanic acid (7).

Figure 1. Metabolic Pathways Requiring Thiamin Pyrophosphate (TPP)



Deficiency

Beriberi, the disease resulting from severe thiamin deficiency, was described in Chinese literature as early as 2600 B.C. Thiamin deficiency affects the cardiovascular, muscular, gastrointestinal, and central and peripheral nervous systems (2). Beriberi has been subdivided into dry, wet, cerebral, or gastrointestinal, depending on the systems affected by severe thiamin deficiency (1, 8).

Dry beriberi

The main feature of dry (paralytic or nervous) beriberi is peripheral neuropathy. Early in the course of the neuropathy, "burning feet syndrome" may occur. Other symptoms include abnormal (exaggerated) reflexes, as well as diminished sensation and weakness in the legs and arms. Muscle pain and tenderness and difficulty rising from a squatting position have also been observed (9).

Wet beriberi

In addition to neurologic symptoms, wet (cardiac) beriberi is characterized by cardiovascular manifestations of thiamin deficiency, which include rapid heart rate, enlargement of the heart, severe swelling (edema), difficulty breathing, and ultimately, congestive heart failure. The Japanese literature describes the acute fulminant form of wet beriberi as "shoshin" (10).

Cerebral beriberi

Cerebral beriberi may lead to Wernicke's encephalopathy and Korsakoff's psychosis, especially in people who abuse alcohol. The diagnosis of Wernicke's encephalopathy is based on a "triad" of signs, which include abnormal eye movements, stance and gait ataxia, and cognitive impairment. Due in part to an overlap of symptoms with alcoholic delirium, Wernicke's encephalopathy is thought to be underdiagnosed (11). If left untreated, the irreversible neurologic damage can cause additional clinical manifestations known as Korsakoff's psychosis. This syndrome – also called Korsakoff's dementia, Korsakoff's amnesia, or amnestic confabulatory syndrome – involves a confused, apathetic state and a profound memory disorder, with severe amnesia and loss of recent and working memory.

Thiamin deficiency affecting the central nervous system is referred to as Wernicke's disease when the amnesic state is not present and Wernicke-Korsakoff syndrome (WKS) when the amnesic symptoms are present along with the eye-movement and gait disorders. Rarer neurologic manifestations can include seizures (12). Most WKS sufferers are alcoholics, although it has been observed in other disorders of gross malnutrition, including stomach cancer and AIDS. Administration of intravenous thiamin to WKS patients generally results in prompt improvement of the eye symptoms, but improvements in motor coordination and memory may be less, depending on how long the symptoms have been present. Evidence of increased immune cell activation and increased free radical production in the areas of the brain that are selectively damaged suggests that oxidative stress plays an important role in the neurologic pathology of thiamin deficiency (13).

Gastrointestinal beriberi

TPP is critical for metabolic reactions that utilize glucose in glycolysis and the citric acid cycle (see **Figure 1**). A decrease in the activity of thiamin-dependent enzymes limits the conversion of pyruvate to acetyl-CoA and the utilization of the citric acid cycle, leading to accumulation of pyruvate and lactate. Lactic acidosis, a condition resulting from the accumulation of lactate, is often associated with nausea, vomiting, and severe abdominal pain in a syndrome described as gastrointestinal beriberi (8).

Causes of thiamin deficiency

Thiamin deficiency may result from inadequate thiamin intake, increased requirement for thiamin, excessive loss of thiamin from the body, consumption of anti-thiamin factors in food, or a combination of these factors.

Inadequate intake

Inadequate consumption of thiamin is the main cause of thiamin deficiency in developing countries (2). Thiamin deficiency is common in low-income populations whose diets are high in carbohydrate and low in thiamin (e.g., milled or polished rice). Breast-fed infants whose mothers are thiamin deficient are vulnerable to developing infantile beriberi. Alcoholism, which is associated with low intake of thiamin among other nutrients, is the primary cause of thiamin deficiency in industrialized countries. Some of the non-alcoholic conditions associated with WKS include anorexia nervosa, bariatric surgery (weight-loss surgery), gastrointestinal malignancies, and malabsorption syndromes (14-17). Obese individuals may also be at heightened risk of thiamin deficiency (18, 19). Moreover, cases of Wernicke's encephalopathy have been linked with hyperemesis gravidarum (severe nausea and vomiting during pregnancy) (20, 21), and with parenteral nutrition lacking vitamin supplementation (22, 23).

Increased requirement

Conditions resulting in an increased requirement for thiamin include strenuous physical exertion, fever, pregnancy, breast-feeding, and adolescent growth. Such conditions place individuals with marginal thiamin intake at risk for developing symptomatic thiamin deficiency.

Malaria patients in Southeast Asia were found to be thiamin deficient more frequently than non-infected individuals (24, 25). Malarial infection leads to a large increase in the metabolic demand for glucose. Because thiamin is required for enzymes involved in glucose metabolism, the stresses induced by malarial infection could exacerbate thiamin deficiency in predisposed individuals. HIV-infected individuals, whether or not they had developed AIDS, were also found to be at increased risk for thiamin deficiency (26). Further, chronic alcohol abuse impairs intestinal absorption and utilization of thiamin (1); thus, alcoholics have increased requirements for thiamin. Thiamin deficiency is also observed as a complication of the refeeding syndrome: the introduction of carbohydrates in severely starved individuals leads to an increased demand for thiamin in glycolysis and the citric acid cycle that precipitates thiamin deficiency (27).

Excessive loss

Excessive loss of thiamin may precipitate thiamin deficiency. By increasing urinary flow, diuretics may prevent reabsorption of thiamin by the kidneys and increase its excretion in the urine (28, 29). The risk of thiamin deficiency is increased in diuretic-treated patients with marginal thiamin intake (30) and in individuals receiving long-term, diuretic therapy (31). Individuals with kidney failure requiring hemodialysis lose thiamin at an increased rate and are at risk for thiamin deficiency (32). Alcoholics who maintain a high fluid intake and high urine flow rate may also experience increased loss of thiamin, exacerbating the effects of low thiamin intake (33).

Anti-thiamin factors (ATF)

The presence of anti-thiamin factors (ATF) in foods contributes to the risk of thiamin deficiency. Certain plants contain ATF, which react with thiamin to form an oxidized, inactive product. Consuming very large amounts of tea or coffee (including decaffeinated), as well as chewing tea leaves and betel nuts, might lower thiamin status due to the presence of ATF (34, 35). ATF include mycotoxins (molds) and thiaminases that break down thiamin in food. Individuals who habitually eat certain raw fresh-water fish, raw shellfish, or ferns are at higher risk of thiamin deficiency because these foods contain thiaminase that normally is inactivated by heat in cooking (1, 6). In Nigeria, an acute, neurologic syndrome (seasonal ataxia) has been associated with thiamin deficiency precipitated by a thiaminase in African silkworms, a traditional, high-protein food for some Nigerians (36).

The Recommended Dietary Allowance (RDA)

The RDA for thiamin, revised in 1998 by the Food and Nutrition Board of the Institute of Medicine, was based on the prevention of deficiency in generally healthy individuals (37; **Table 1**).

Table 1. Recommended Dietary Allowance (RDA) for Thiamin

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	0.2 (AI)	0.2 (AI)
Infants	7-12 months	0.3 (AI)	0.3 (AI)
Children	1-3 years	0.5	0.5
Children	4-8 years	0.6	0.6
Children	9-13 years	0.9	0.9
Adolescents	14-18 years	1.2	1.0
Adults	19 years and older	1.2	1.1
Pregnancy	all ages	-	1.4
Breast-feeding	all ages	-	1.4

Disease Prevention

Cataracts

A cross-sectional study of 2,900 Australian men and women, 49 years of age and older, found that those in the highest quintile of thiamin intake were 40% less likely to have nuclear cataracts than those in the lowest quintile (38). In addition, a study in 408 US women found that higher dietary intakes of thiamin were inversely associated with five-year change in lens opacification (39). However, these cross-sectional associations have yet to be elucidated by studies of causation.

Diabetes mellitus and vascular complications

Patients with diabetes mellitus have been reported to have low plasma concentrations and high renal clearance of thiamin (40, 41), suggesting that individuals with type 1 or type 2 diabetes are at increased risk for thiamin deficiency. Two thiamin transporters, thiamin transporter-1 (THTR-1) and THTR-2, are involved in thiamin uptake by enterocytes in the small intestine and re-uptake in the proximal tubules of the kidneys. One study suggested that hyperglycemia in patients with diabetes could affect thiamin re-uptake by decreasing the expression of thiamin transporters in the kidneys (42). Conversely, thiamin deficiency appears to impair the normal endocrine function of the pancreas and exacerbate hyperglycemia. Early studies showed that insulin synthesis and secretion were altered in the endocrine pancreatic cells of thiamin-deficient rats (43, 44). In humans, thiamin deficiency caused by recessive mutations in the gene encoding THTR-1 leads to diabetes mellitus in the thiamin-responsive megaloblastic anemia syndrome (see Metabolic diseases below).

In a randomized, double-blind pilot study, high-dose thiamin supplements (300 mg/day) were given for six weeks to hyperglycemic individuals (either glucose intolerant or newly diagnosed with type 2 diabetes). Thiamin supplementation prevented any further increase in fasting glucose and insulin concentrations compared with placebo treatment but did not reduce the hyperglycemia (45). However, one study suggested that thiamin supplementation might improve fasting glucose concentrations in in early stages of type 2 diabetes (i.e., pre-diabetes) (46).

Disease Treatment

Alzheimer's disease

Some older adults are at increased risk for developing subclinical thiamin deficiency secondary to poor dietary intake, reduced gastrointestinal absorption, and multiple medical conditions (47, 48). Since thiamin deficiency can result in a form of dementia (Wernicke-Korsakoff syndrome), its relationship to Alzheimer's disease (AD) and other forms of dementia have been investigated. AD is characterized by a decline in cognitive function in elderly people, accompanied by pathologic features that include β-amyloid plaque deposition and neurofibrillary tangles formed by hyperphosphorylated Tau protein (49).

Using positron emission tomography (PET) scanning, reduced glucose metabolism has been observed in brains of AD patients (50). A large, multicenter PET study using a radiolabeled glucose analog, 18F-Fluoro-deoxyglucose (FDG), correlated a reduction in FDG uptake (a surrogate marker for glucose metabolism) with the extent of cognitive impairment in AD patients. This study, which included 822 subjects over 55 years of age that were cognitively normal (n=229), displayed mild cognitive impairment (n=405), or had mild AD (n=188), demonstrated that brain glucose utilization could predict the progression from mild cognitive impairment to AD (51). A nine-year longitudinal study associated the presence of diabetes mellitus in older people (above 55 years old) with an increased risk for developing AD (52). Emerging evidence links type 2 diabetes and AD, conditions that may involve insulin resistance in the brain (reviewed in 53).

A reduction in thiamin-dependent processes in the brain appears to be related to the altered glucose metabolism in patients with AD (54-56). Case-control studies have found blood levels of thiamin, TPP, and TMP to be lower in those with dementia of Alzheimer's type (DAT) compared to control subjects (57, 58). Moreover, several investigators have found evidence of decreased activity of TPP-dependent enzymes, α-ketoglutarate dehydrogenase and transketolase, in the brains of patients who died of AD (59). The finding of decreased brain levels of TPP in the presence of normal levels of free thiamin and TMP suggests altered TPP synthesis rather than poor thiamin bioavailability. However, it is not clear whether the activities of TPP-metabolizing enzymes (including thiamin pyrophoskinase) are altered in AD patients (60, 61). Chronic administration of the thiamin derivative benfotiamine alleviated cognitive alterations and decreased the number of β-amyloid plaques in a mouse model of AD without increasing TMP and TPP levels in the brain. This suggested that the beneficial effects of benfotiamine in the brain were likely mediated by the stimulation of TPP-independent pathways (62). Chronic benfotiamine administration was also shown to decrease the number of neurofibrillary tangles in certain brain regions and improve survival in a mouse model (63). In a rat model of neurodegeneration, long-term oral benfotiamine supplementation increased thiamin pyrophosphate concentrations and led to improvements in insulin signaling and cognitive deficits (64).

Thiamin deficiency has been linked to increased β-amyloid production in cultured neuronal cells and to plaque formation in animal models (65, 66). These pathological hallmarks of AD could be reversed by thiamin supplementation, suggesting that thiamin could be protective in AD. Other disorders, including mitochondrial dysfunction and chronic oxidative stress, have been linked to both thiamin deficiency and AD pathogenesis and progression (13, 55, 67). Presently, there is only slight and inconsistent evidence that thiamin supplements are of benefit in AD. A double-blind, placebo-controlled study of 15 patients (10 completed the study) reported no beneficial effect of 3 grams/day of thiamin on cognitive decline over a 12-month period (68). A preliminary report from another study claimed a mild benefit of 3 to 8 grams of thiamin per day in DAT, but no additional data from that study are available (69). A mild beneficial effect in patients with AD was reported after 12 weeks of treatment with 100 mg/day of a thiamin derivative (thiamin tetrahydrofurfuryl disulfide), but this study was not placebo-controlled (70). A 2001 systematic review of randomized, double-blind, placebo-controlled trials of thiamin in patients with DAT found no evidence that thiamin was a useful treatment for the symptoms of Alzheimer's disease (71). More recently, a small uncontrolled study in five patients with mild-to-moderate AD reported cognitive improvement, measured by the Mini-Mental Status Examination, following supplementation with 300 mg/day of benfotiamine for 18 months (72). In a placebo-controlled study of 70 β-amyloid positive patients with either amnestic mild cognitive impairment (a precursor to AD) or mild AD, those receiving 600 mg/day of benfotiamine for 12 months experienced less cognitive decline compared to placebo, but the differences did not reach statistical significance (p=0.125; 73). Large-scale, randomized controlled trials are needed to determine whether supplemental thiamin or benfotiamine might help slow progression of cognitive decline in those with Alzheimer's disease.

Huntington's disease

Huntington's disease is an inherited neurodegenerative disorder characterized by selective degeneration of nerve cells known as striatal spiny neurons. Symptoms, such as movement disorders and impaired cognitive function, typically develop in the fourth decade of life and progressively deteriorate over time. A recent study found decreased levels of the thiamin transporter-2 (THTR-2) protein in the striatum and frontal cortex of patients with Huntington's disease compared to age-and sex-matched healthy controls (74). Compared to control subjects, this study also found lower concentrations of TPP in the striatum and lower concentrations of TMP in the cerebrospinal fluid of patients with Huntington's disease (74). Mutations in the *SLC19A3* gene that encodes THTR-2 causes biotin-thiamin-responsive basal ganglia disease, which is treated with high-dose co-supplementation with biotin and thiamin for life (see Biotin-thiamin-responsive basal ganglia disease below). In a mouse model of Huntington's disease, high-dose supplementation with both of these vitamins improved neuropathological and motor deficits but had no effect on lifespan (p=0.15) (74). A phase II, open-label clinical trial evaluating the effect of combined thiamin-biotin supplementation, at moderate (600 mg/day of thiamin and 150 mg/day of biotin) and high (1,200 mg/day of thiamin and 300 mg/day of biotin) dosages, in Huntington's disease is currently underway (75).

Congestive heart failure

Severe thiamin deficiency (wet beriberi) can lead to impaired cardiac function and ultimately congestive heart failure (CHF). Although cardiac manifestations of beriberi are rarely encountered in industrialized countries, CHF due to other causes is common, especially in the elderly. Loop diuretics used in the treatment of CHF, notably furosemide, increase thiamin excretion, potentially leading to thiamin deficiency (76, 77). Patients with CHF might also have altered thiamin metabolism, including reduced absorption of thiamin in the small intesine (78). A 2015 meta-analysis of nine observational studies found a 2.5 times higher risk of thiamin deficiency in patients with heart failure compared to control subjects (78). As in the general population, older CHF patients were found to be at higher risk of thiamin deficiency than younger ones (79).

An important measure of cardiac function in CHF is the left ventricular ejection fraction (LVEF), which can be assessed by echocardiography. One study in 25 patients found that furosemide use at doses of 80 mg/day or greater was associated with a 98% prevalence of thiamin deficiency (31). In a randomized, double-blind study of 30 CHF patients, all of whom had been taking furosemide (80 mg/day) for at least three months, intravenous (IV) thiamin therapy (200 mg/day) for seven days resulted in an improved LVEF compared to IV placebo (80). When all 30 of the CHF patients in that study subsequently received six weeks of oral thiamin therapy (200 mg/day), the average LVEF improved by 22%. This finding may be relevant because improvements in LVEF have been associated with improved survival in CHF patients (81). However, clinical trials of oral thiamin supplementation in heart failure patients have not found any benefit. In a randomized, double-blind, placebo-controlled trial in 52 patients with systolic heart failure, 300 mg/day of supplemental thiamin for one month did not improve LVEF compared to placebo (82). A randomized, double-blind, placebo-controlled trial in 64 patients with heart failure reported that 200 mg/day or supplemental thiamin for six months did not improve LVEF (83).

Although little evidence supports the routine use of supplemental thiamin in CHF patients, trials specifically in CHF patients with marginal thiamin status have not been done, and some suggest that it may be prudent to screen patients on long-term diuretic therapy for thiamin deficiency and treat accordingly (84).

Type 2 diabetes mellitus and vascular complications

Chronic hyperglycemia in individuals with diabetes mellitus contributes to the pathogenesis of microvascular diseases. Diabetes-related vascular damage can affect the heart (cardiomyopathy), kidneys (nephropathy), retina (retinopathy), and peripheral nervous system (neuropathy). In subjects with diabetes, hyperglycemia alters the function of bone marrow-derived endothelial progenitor cells (EPC) that are critical for the growth of blood vessels (85). Interestingly, a higher daily intake of thiamin from the diet was correlated with more circulating EPC and with better vascular endothelial health in 88 individuals with type 2 diabetes (86). An inverse association has also been found between plasma concentrations of thiamin and the presence of soluble vascular adhesion molecule-1 (sVCAM-1), a marker of vascular dysfunction, in patients with diabetes (40, 87). Early markers of diabetic nephropathy include the presence of serum albumin in the urine, known as microalbuminuria. Administration of thiamin or benfotiamine (a thiamin derivative) prevented the development of renal complications in chemically-induced diabetic rats (88). A randomized, double-blind, placebo-controlled study conducted in 40 patients with type 2 diabetes with microalbuminuria found that high-dose thiamin supplementation (300 mg/day) decreased excretion of urinary albumin over a three-month period (87). Since thiamin treatment has shown promising results in cultured cells and animal models (89-91), the effects of thiamin and its derivatives on vascular complications should be examined in patients with diabetes.

Cancer

Thiamin deficiency and Wernicke-Korsakoff syndrome have been observed in some cancer patients with rapidly growing tumors (92, 93). Research in cell culture and animal models indicates that rapidly dividing cancer cells have a high requirement for thiamin (94). All rapidly dividing cells require nucleic acids at an increased rate, and some cancer cells appear to rely heavily on the TPP-dependent enzyme, transketolase, to provide the ribose-5-phosphate necessary for nucleic acid synthesis. One study found that the levels of THTR-1, transketolase, and TPP mitochondrial transporters were increased in samples of human breast cancer tissue compared to normal tissue, suggesting an adaptation in thiamin homeostasis in support of cancer metabolism (95). Other studies have found that the gene encoding THTR-2 is downregulated in certain cancers (96). Moreover, use of the chemotherapeutic drug, 5-fluorouracil, inhibits phosphorylation of thiamin to thiamin pyrophosphate and may thus lead to thiamin deficiency (97, 98).

Thiamin supplementation in cancer patients is common to prevent thiamin deficiency, but Boros et al. caution that too much thiamin may actually fuel the growth of some malignant tumors (99), suggesting that thiamin supplementation be reserved for those cancer patients who are actually deficient in thiamin. Presently, there is no evidence available from studies in humans to support or refute this theory. However, it would be prudent for individuals with cancer who are considering thiamin supplementation to discuss it with the clinician managing their cancer therapy. Intravenous, high-dose thiamin has been suggested as a treatment for cancer patients with confirmed Wernicke-Korsakoff (93).

Sepsis

Sepsis is a life-threatening critical illness caused by a dysregulated host response to an infection. The widespread inflammation can lead to tissue and organ damage and to death (100). Because thiamin deficiency is common among septic patients (101), several studies have investigated the treatment effect of intravenous thiamin – alone or in combination with other agents like vitamin C and hydrocortisone.

Observational studies examining the association of intravenous thiamin as a monotherapy have mainly looked at its association with lactic acidosis, which commonly occurs in both thiamin deficiency and sepsis, and with mortality. One retrospective study in 123 septic patients and 246 matched controls found that intravenous thiamin administration within 24 hours of hospital admission was linked to improvements in both lactate clearance and 28-day mortality (102). In a small retrospective study of 53 alcohol-use disorder patients presenting with septic shock, lower mortality was observed in the 34 patients who received intravenous thiamin compared to the 19 patients who did not (103).

A few randomized controlled trials have evaluated the effect of intravenous thiamin in the treatment of sepsis. A randomized, double-blind, placebo-controlled trial in 88 patients with sepsis and elevated blood concentrations of lactate reported that intravenous thiamin (200 mg twice daily for seven days or until discharge from the hospital) did not decrease lactate concentrations at 24 hours post initiation of treatment – the primary endpoint of the trial (104). No differences between the treatment and placebo groups were found for the secondary endpoints, which included survival (104). In a subsequent analysis of data from this trial, the septic patients that were given parenteral thiamin (n=31) had lower creatinine concentrations throughout the treatment and were less likely to need renal replacement therapy compared to placebo (n=39; 105).

A 2020 meta-analysis of four studies – one observational and three randomized controlled trials – found no benefit of intravenous thiamin for improving lactate concentrations, length of hospital stay in intensive care, or overall survival (106). Large-scale clinical trials are needed to determine whether parenteral administration of thiamin is beneficial in the treatment of sepsis. Administering thiamin in combination with vitamin C and corticosteroids may be more efficacious to treat sepsis (107); some clinical trials of such treatments are currently underway (see clinicaltrials.gov/).

Metabolic diseases

Thiamin supplementation is included in the clinical management of genetic diseases that affect the metabolism of carbohydrates and branched-chain amino acids (BCAAs).

Thiamin-responsive pyruvate dehydrogenase complex (PDHC) deficiency

Mutations in PDHC prevent the efficient oxidation of carbohydrates in affected individuals. PDHC deficiency is commonly characterized by lactic acidosis, neurologic and neuromuscular degeneration, and death during childhood. The patients who respond to thiamin treatment (from a few mg/day to doses above 1,000 mg/day) exhibit PDHC deficiency due to the decreased affinity of PDHC for TPP (108, 109). Although thiamin supplementation can reduce lactate accumulation and improve the clinical features in thiamin-responsive patients, it does not constitute a cure (110).

Maple syrup urine disease

Inborn errors of BCAA metabolism lead to thiamin-responsive branched-chain ketoaciduria, also known as maple syrup urine disease. Alterations in the BCAA catabolic pathway result in neurologic dysfunction caused by the accumulation of BCAAs and their derivatives, branched-chain ketoacids (BCKA). The therapeutic approach includes a synthetic diet with reduced BCAA content, and thiamin (10-1,000 mg/day) is supplemented to patients with mutations in the E2 subunit of the BCKDH complex (111). In thiamin-responsive individuals, the supplementation has been proven effective to correct the phenotype without recourse to the BCAA restriction diet.

Thiamin-responsive megaloblastic anemia

Mutations in the *SLC19A2* gene that encodes THTR-1 impairs intestinal thiamin uptake and causes thiamin deficiency, leading to thiamin-responsive megaloblastic anemia (112). This syndrome, which is also called thiamin metabolism dysfunction syndrome-1, is characterized by megaloblastic anemia, diabetes mellitus, and deafness. A review of 30 cases reported additional neurologic, visual, and cardiac impairments (113). High-dose oral supplementation with thiamin (up to 300 mg/day) helps to maintain health and correct hyperglycemia in prepubescent children. A recent study in 32 individuals with found no additional benefit of oral doses above 150 mg/day (114). After puberty, a decline in pancreatic function results in the requirement of insulin together with thiamin to control the hyperglycemia. One study also reported that the treatment of a four-month-old girl with 100 mg/day of thiamin did not prevent hearing loss at 20 months of age (115). Early diagnosis of the syndrome and early treatment with thiamin is important for a better prognosis (114).

Biotin-thiamin-responsive basal ganglia disease

Biotin-thiamin-responsive basal ganglia disease (also called biotin-responsive basal ganglia disease, thiamin transporter-2 deficiency, and thiamin metabolism dysfunction syndrome-2) is caused by an autosomal recessive mutation in the *SLC19A3* gene that codes for THTR-2. The disease usually presents around 3 to 10 years of age (116), but an early infantile form of the disease exists with onset as early as one month of age (117). Clinical features include subacute encephalopathy (confusion, drowsiness, altered level of consciousness), ataxia, and seizures.

A retrospective study of 18 affected individuals from the same family or the same tribe in Saudi Arabia showed that biotin monotherapy (5-10 mg/kg/day) efficiently abolished the clinical manifestations of the disease, although one-third of the patients suffered from recurrent acute crises. Often associated with poor outcomes, acute crises were not observed for a five-year follow-up period following thiamin supplementation (300-400 mg/day) – early diagnosis and immediate treatment with biotin and thiamin led to positive outcomes (118). Recent studies have found supplemental thiamin to be important in treating the condition. In an open-label study of 20 pediatric patients with the disease, supplemental thiamin alone was as effective as combined biotin-thiamin supplementation when given for 30 months (119). Lifelong high-dose supplementation with a combination of biotin and thiamin is generally the treatment for biotin-thiamin-responsive basal ganglia disease (116). Early diagnosis and treatment is important to ensure a better prognosis (117, 120).

Other thiamin metabolism dysfunction syndromes

Supplemental thiamin has limited utility in treating other inborn errors of thiamin metabolism. Mutations in the *SLC25A19* gene that codes for the mitochondrial TPP transporter can result in either thiamin metabolism dysfunction syndrome-3 (THMD3) or thiamin metabolism dysfunction syndrome-4 (THMD4). Of these rare syndromes, THMD3 (also called Amish-type microcephaly or Amish lethal microcephaly) has the more severe phenotype, resulting in a congenital microcephaly, elevated concentrations of α-ketoglutarate in urine, and usually death in infancy (121). THMD4 is characterized by episodic encephalopathy and weakness, which often presents following a viral infection or febrile illness in childhood. Some patients affected with THMD4 may respond to high-dose thiamin supplementation (122).

Mutations in the *TPK1* gene result in thiamin pyrophosphokinase 1 deficiency and thiamin metabolism dysfunction syndrome-5 (THMD5), which usually manifests in early childhood. While the clinical presentation of THMD5 varies, affected individuals often experience episodic ataxia, dystonia, and lactic acidosis (123). Only a few cases of THMD5 have been reported to date; two of these patients experienced limited improvement of symptoms upon supplementation with thiamin, in conjunction with adherence to a high-fat diet (124).

Sources

Humans obtain thiamin from dietary sources and from the normal microflora of the colon, although the contribution of the latter towards the body's requirement for thiamin is not clear (125).

Food sources

A varied diet should provide most individuals with adequate thiamin to prevent deficiency. In the US the average dietary thiamin intake for young adult men is about 2 mg/day and 1.2 mg/day for young adult women. A survey of people over the age of 60 found an average dietary thiamin intake of 1.4 mg/day for men and 1.1 mg/day for women (37). However, institutionalization and poverty both increase the likelihood of inadequate thiamin intake in the elderly (126). Whole-grain cereals, legumes (e.g., beans and lentils), nuts, lean pork, and yeast are rich sources of thiamin (1). Because most of the thiamin is lost during the production of white flour and polished (milled) rice, white rice and foods made from white flour (e.g., bread and pasta) are fortified with thiamin in many Western countries. A number of thiamin-rich foods are listed in the table below, along with their thiamin content in milligrams (mg). For more information on the nutrient content of foods, search USDA's FoodData Central.

Table 2. Some Food Sources of Thiamin

Food	Serving	Thiamin (mg)
Lentils (cooked, boiled)	½ cup	0.17
Green peas (cooked, boiled)	½ cup	0.21
Long-grain, brown rice (cooked)	½ cup	0.18
Long-grain, white rice, enriched (cooked)	½ cup	0.13
Long-grain, white rice, unenriched (cooked)	½ cup	0.016
Whole-wheat bread	1 slice	0.13
White bread, enriched	1 slice	0.31
Fortified breakfast cereal (wheat, puffed)	1 cup	0.31
Wheat germ breakfast cereal (toasted, plain)	1 cup	1.88
Pork, lean (loin, tenderloin, cooked, roasted)	3 ounces*	0.80
Pecans	1 ounce (19 halves)	0.19
Spinach (cooked, boiled)	½ cup	0.09
Orange	1 fruit	0.11
Cantaloupe	½ fruit	0.11
Milk	1 cup	0.10
Egg (cooked, hard-boiled)	1 large	0.03
*Three ounces of meat is a serving about the size of a deck of cards		

Supplements

Thiamin is available in dietary supplements and in fortified foods, most commonly as thiamin hydrochloride or thiamin mononitrate (127). Multivitamin supplements typically contain at least 1.2 mg of thiamin, the Daily Value (DV) for adults and children 4 years and older (128).

Benfotiamine is a synthetic, lipid-soluble precursor of thiamin that is available as a dietary supplement. It has higher bioavailability compared to thiamin (129).

Safety

Toxicity

The Food and Nutrition Board did not set a tolerable upper intake level (UL) for thiamin because there are no well-established toxic effects from consumption of excess thiamin in food or through long-term, oral supplementation (up to 200 mg/day). A small number of life-threatening anaphylactic reactions have been observed with large intravenous doses of thiamin (37).

Drug interactions

Reduced blood concentrations of thiamin have been reported in individuals with seizure disorders (epilepsy) taking the anticonvulsant medication, phenytoin, for long periods of time (130). 5-Fluorouracil, a drug used in cancer therapy, inhibits the phosphorylation of thiamin to TPP (131). Diuretics, especially furosemide, may increase the risk of thiamin deficiency in individuals with marginal thiamin intake due to increased urinary excretion of thiamin (29). Moreover, chronic alcohol abuse is associated with thiamin deficiency due to low dietary intake, impaired absorption and utilization, and increased excretion of the vitamin (1). Chronic alcohol feeding to rats showed a decrease in the active absorption of thiamin linked to the inhibition of thiamin membrane transporter THTR-1 in the intestinal epithelium (132). Alcohol consumption in rats also decreases the levels of THTR-1 and THTR-2 in renal epithelial cells, thus limiting thiamin re-uptake by the kidneys (133).

Linus Pauling Institute Recommendation

The Linus Pauling Institute supports the recommendation by the Food and Nutrition Board of 1.2 mg/day of thiamin for men and 1.1 mg/day for women. A varied diet should provide enough thiamin for most people. Following the Linus Pauling Institute recommendation to take a daily multivitamin/mineral supplement, containing 100% of the Daily Values (DV), will ensure an intake of at least 1.5 mg/day of thiamin.

Older adults (>50 years)

Presently, there is no evidence that the requirement for thiamin is increased in older adults, but some studies have found inadequate dietary intake and thiamin insufficiency to be more common in elderly populations (126). Thus, it would be prudent for older adults to take a multivitamin/mineral supplement, which will generally provide at least 1.5 mg/day of thiamin.

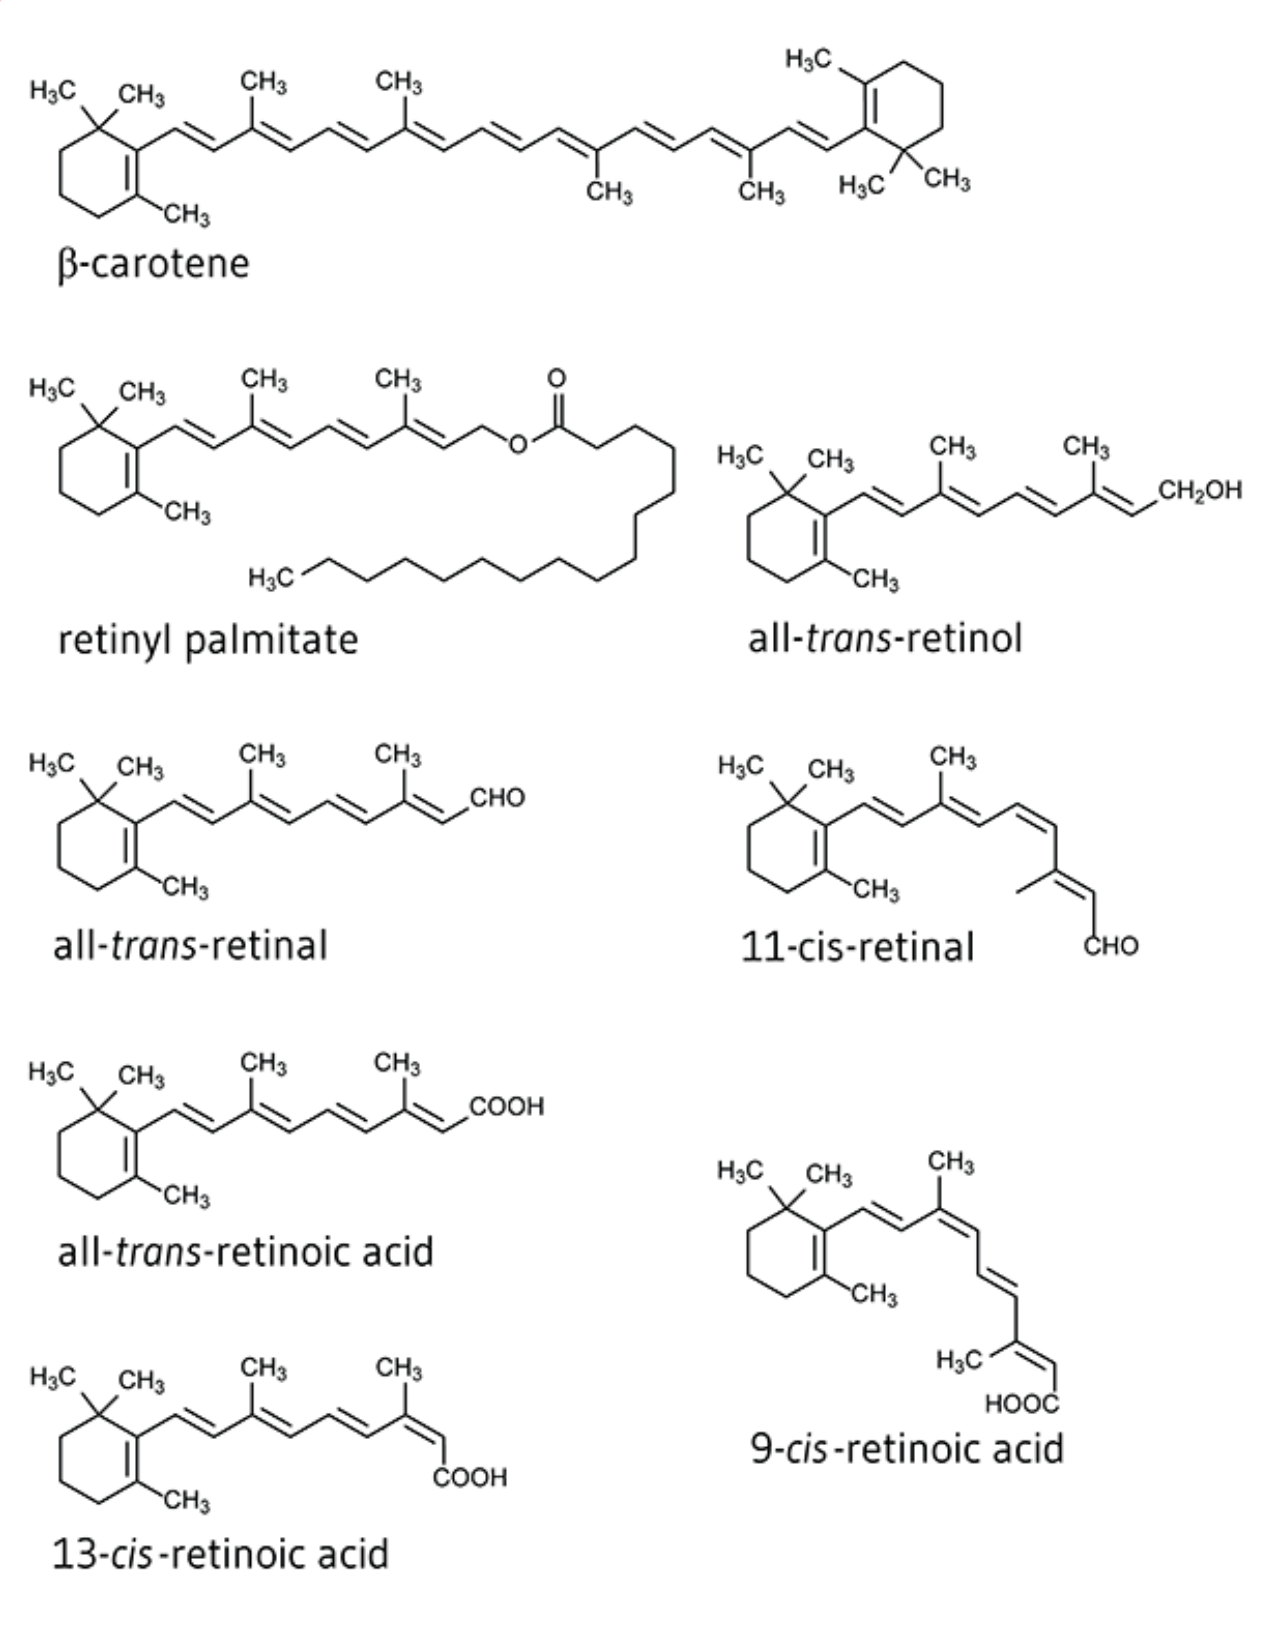
Summary

- Vitamin A is a generic term that refers to fat-soluble compounds found as preformed vitamin A (retinol) in animal products and as provitamin A carotenoids in fruit and vegetables. The three active forms of vitamin A in the body are retinol, retinal, and retinoic acid. *(More information)*
- Vitamin A is involved in regulating the growth and specialization (differentiation) of virtually all cells in the human body. Vitamin A has important roles in embryonic development, organ formation during fetal development, normal immune functions, and eye development and vision. *(More information)*
- Vitamin A deficiency is a major cause of preventable blindness in the world. It is most prevalent among children and women of childbearing age. Vitamin A deficiency is associated with an increased susceptibility to infections, as well as to thyroid and skin disorders. *(More information)*
- The recommended dietary allowance (RDA) is 700 micrograms of retinol activity equivalents (μg RAE)/day for women and 900 μg RAE/day for men. *(More information)*
- Vitamin A prophylaxis appears to significantly reduce childhood mortality in regions at high risk of vitamin A deficiency. Further, high-dose vitamin A supplementation is widely recommended for children over six months of age when they are infected with measles while malnourished, immunodeficient, or are at risk of measles complications. *(More information)*
- Retinoic acid and analogs are used at pharmacological doses in the treatment of acute promyelocytic leukemia and various skin diseases. *(More information)*
- Animal food sources rich in preformed vitamin A include dairy products, liver, and fish oils; fortified cereals may also contain preformed vitamin A. Rich sources of provitamin A carotenoids include orange and green vegetables, such as sweet potato and spinach. *(More information)*
- Overconsumption of preformed vitamin A can be highly toxic and is especially contraindicated prior to and during pregnancy as it can result in severe birth defects. The tolerable upper intake level (UL) for vitamin A in adults is set at 3,000 μg RAE/day. The UL does not apply to vitamin A derived from carotenoids. *(More information)*

Vitamin A is a generic term that encompasses a number of related compounds (**Figure 1**). Retinol and retinyl esters are often referred to as preformed vitamin A. Retinol can be converted by the body to retinal, which can be in turn be oxidized to retinoic acid, the form of vitamin A known to regulate gene transcription. Retinol, retinal, retinoic acid, and related compounds are known as retinoids. β-Carotene and other food carotenoids that can be converted by the body into retinol are referred to as provitamin A carotenoids (see the article on Carotenoids). Hundreds of different carotenoids are synthesized by plants, but only about 10% of them are capable of being converted to retinol (1). The following discussion will focus mainly on preformed vitamin A compounds and retinoic acid.

Figure 1. Chemical Structures



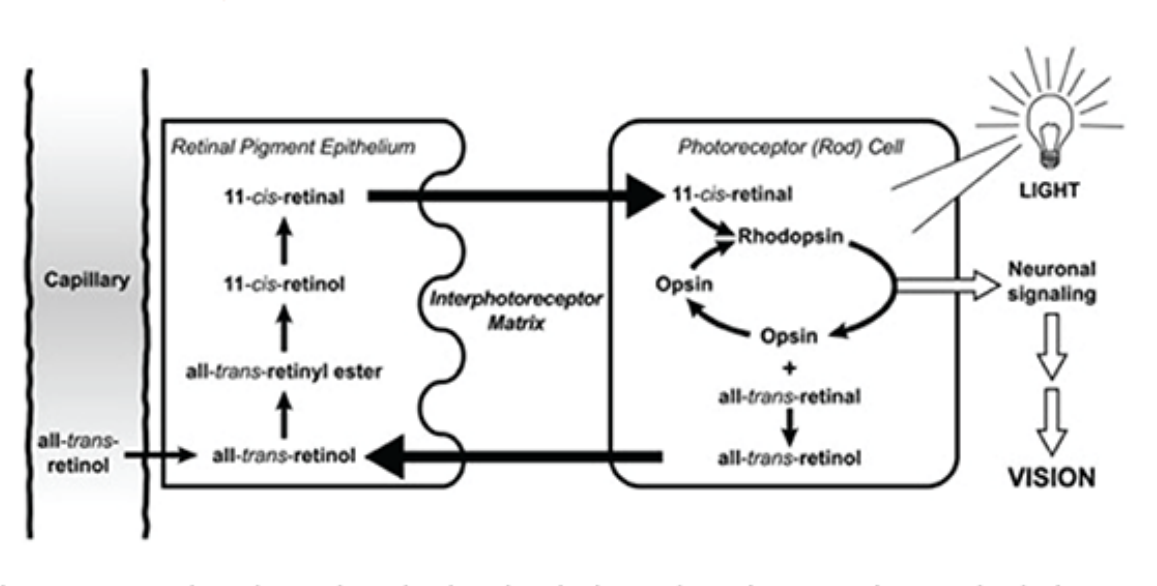
Function

Vitamin A compounds are essential fat-soluble molecules predominantly stored in the liver in the form of retinyl esters (e.g., retinyl palmitate). When appropriate, retinyl esters are hydrolyzed to generate all-*trans*-retinol, which binds to retinol binding protein (RBP) before being released in the bloodstream. The all-*trans*-retinol/RBP complex circulates bound to the protein, transthyretin, which delivers all-*trans*-retinol to peripheral tissues (reviewed in 2). Vitamin A as retinyl esters in chylomicrons was also found to have an appreciable role in delivering vitamin A to extrahepatic tissues, especially in early life (3, 4).

Visual system and eyesight

Located at the back of the eye, the retina contains two main types of light-sensitive receptor cells – known as rod and cone photoreceptor cells. Photons (particles of light) that pass through the lens are sensed by the photoreceptor cells of the retina and converted to nerve impulses (electric signals) for interpretation by the brain. All-*trans*-retinol is transported to the retina via the circulation and accumulates in retinal pigment epithelial (RPE) cells (**Figure 2**) (5). Here, all-*trans*-retinol is esterified to form a retinyl ester, which can be stored. When needed, retinyl esters are broken apart (hydrolyzed) and isomerized to form 11-*cis*-retinol, which can be oxidized to form 11-*cis*-retinal. 11-*cis*-retinal can be shuttled across the interphotoreceptor space to the rod photoreceptor cell that is specialized for vision in low-light conditions and for detection of motion. In rod cells, 11-*cis*-retinal binds to a protein called opsin to form the visual pigment rhodopsin (also known as visual purple). Absorption of a photon of light catalyzes the isomerization of 11-*cis*-retinal to all-*trans*-retinal that is released from the opsin molecule. This photoisomerization triggers a cascade of events, leading to the generation of a nerve impulse conveyed by the optic nerve to the brain's visual cortex. All-*trans*-retinal is converted to all-*trans*-retinol and transported across the interstitial space to the RPE cells, thereby completing the visual cycle.

Figure 2. The Visual Cycle



Retinol is transported to the retina via the circulation, where it moves into retinal pigment epithelial cells. There, retinol is esterified to form a retinyl ester that can be stored. When needed, retinyl esters are broken apart (hydrolyzed) and isomerized to form 11-*cis*-retinol, which can be oxidized to form 11-*cis*-retinal. 11-*cis*-retinal can be shuttled to the rod cell, where it binds to a protein called opsin to form the visual pigment, rhodopsin (also known as visual purple). Absorption of a photon of light catalyzes the isomerization of 11-*cis*-retinal to all-*trans*-retinal and results in its release. This isomerization triggers a cascade of events, leading to the generation of an electrical signal to the optic nerve. The nerve impulse generated by the optic nerve is conveyed to the brain where it can be interpreted as vision. Once released, all-*trans*-retinal is converted to all-*trans*-retinol, which can be transported across the interphotoreceptor matrix to the retinal epithelial cell to complete the visual cycle.

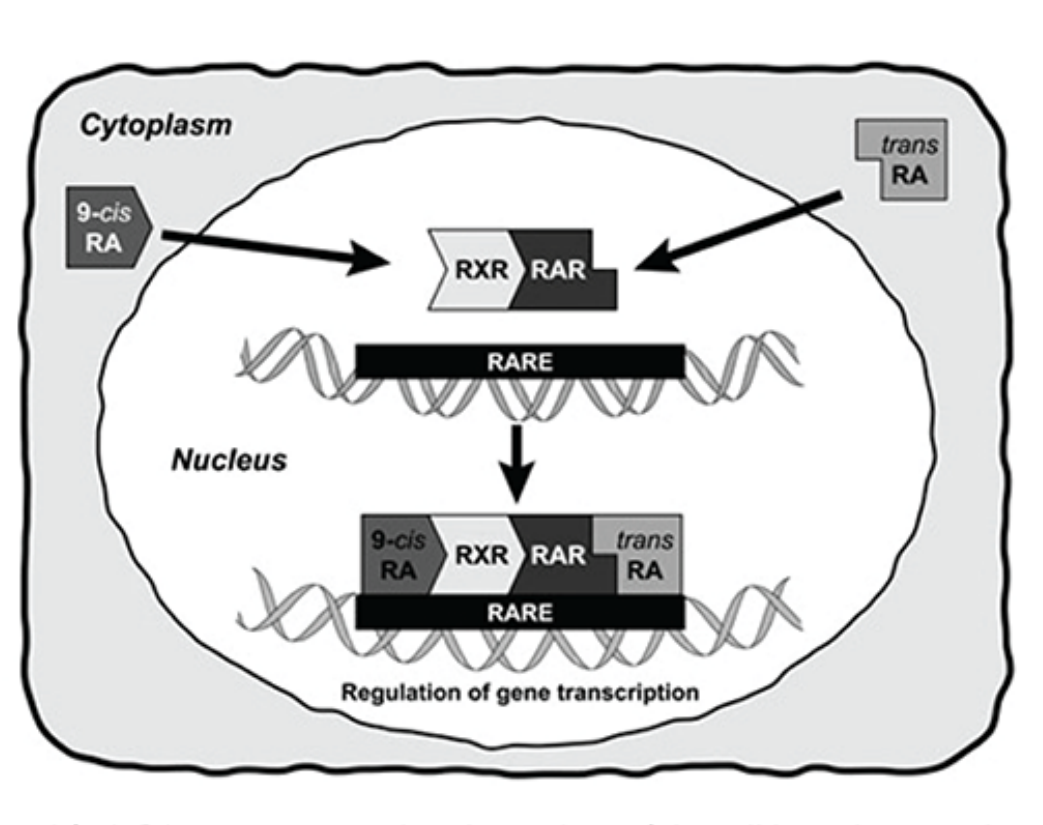
A similar cycle occurs in cone cells that contain red, green, or blue opsin proteins required for the absorption of photons from the visible light spectrum (2). Vitamin A is also essential for mammalian eye development (6). Thus, because vitamin A is required for the normal functioning of the retina, dim-light vision, and color vision, inadequate retinol and retinal available to the retina result in impaired dark adaptation. In the severest cases of vitamin A deficiency, thinning and ulceration of the cornea leads to blindness (see Deficiency).

Regulation of gene expression

Regulatory capacity of retinoic acid

In cells, all-*trans*-retinol can be either stored (in the form of retinyl ester) or oxidized to all-*trans*-retinal by alcohol dehydrogenases. In turn, retinaldehyde dehydrogenases can catalyze the conversion of all-*trans*-retinal into two biologically active isomers of retinoic acid (RA): all-*trans*-RA and 9-*cis*-RA. RA isomers act as hormones to affect gene expression and thereby influence numerous physiological processes. All-*trans*-RA and 9-*cis*-RA are transported to the nucleus of the cell bound to cellular retinoic acid-binding proteins (CRABP). Within the nucleus, RA isomers bind to specific nuclear receptor proteins that are ligand-dependent transcription factors (**Figure 3**). Both all-*trans*-RA and 9-*cis*-RA can bind to retinoic acid receptors (RARα, RARβ, and RARγ), whereas only 9-*cis*-RA binds to retinoid X receptors (RXRα, RXRβ, and RXRβ) (7). RAR and RXR subtypes form either complexes of two of the same protein (RAR/RAR and RXR/RXR homodimers) or complexes of two different proteins (RAR/RXR heterodimers). RAR/RXR heterodimers can bind to a regulatory DNA sequence called retinoic acid response element (RARE) located within the promoter of retinoid-responsive genes. The transcriptional activity of RAR/RXR heterodimers appears to be mainly driven by the binding of all-*trans*-RA to RAR.

Figure 3. A Simplified Model of the Regulation of Gene Expression by Retinoic Acid (RA) Isomers



All-*trans*-RA and 9-*cis*-RA are transported to the nucleus of the cell bound to cytoplasmic retinoic acid-binding proteins. Within the nucleus, all-*trans*-RA binds to retinoic acid receptors (RAR) and 9-*cis*-RA binds to retinoid receptors (RXR). RAR and RXR form RAR/RXR heterodimers, which bind to regulatory regions of the chromosome called retinoic acid response elements (RARE). Binding of all-*trans*-RA and 9-*cis*-RA to RAR and RXR respectively allows the complex to regulate the rate of gene transcription.

The activation of RAR by RA binding triggers the recruitment of transcriptional coregulators to target promoters, thereby inhibiting or allowing the transcription of genes (8). RXR also forms heterodimers with several other nuclear receptors, including thyroid hormone receptor (TR), vitamin D receptor (VDR), steroid receptors, and peroxisome proliferator-activated receptor (PPAR) (9). In this way, vitamin A may interact with thyroid hormone, vitamin D, steroids (e.g., estrogen), or PPAR ligands signaling pathways and influence the transcription of a broad range of genes.

There is also evidence that RA/RAR can affect gene expression in a RARE-independent manner. For example, it was reported that RAR could interfere with TGFβ/Smad signaling pathway through direct interaction of RAR with the heterodimeric transcription factor, Smad3/Smad4. In the absence of RA, RAR was found to act as a coactivator of Smad3/Smad4-mediated transcription, while RAR agonists repressed the transcriptional activity of Smad3/Smad4 (10). In retinoblastoma cells, RAR was also involved in RA-induced activation of signaling cascades mediated by tyrosine kinases known as phosphoinositide 3-kinase (PI3K) and leading to cell differentiation (11, 12). RA also appeared to induce neuronal differentiation by activating ERK1/2 MAP kinase signaling pathway that phosphorylated transcription factor, CREB (cyclic AMP response element binding protein). Phosphorylated CREB can subsequently bind to the CREB response element in the promoter of genes involved in cell differentiation (13). Also, independently of RAR, RA was found to inhibit ERK1/2 phosphorylation/activation and subsequent AP1-mediated expression of interleukin-6 in synovial cells (14). Hence, RA can influence the expression of genes whose promoters do not contain RARE.

By regulating the expression of over 500 retinoid-responsive genes (including several genes involved in vitamin A metabolism itself), retinoic acid isomers play major roles in cellular proliferation and differentiation (i.e., cell commitment to highly specialized functions).

Regulatory capacity of retinol

In the eye and tissues like white adipose and muscle, retinol plasma membrane receptor/transporter STRA6 accepts retinol from extracellular RBP and unloads it to intracellular retinol-binding protein (CRBP). STRA6 also cooperates with lecithin:retinol acyltransferase (LRAT), an enzyme that catalyzes retinol esterification and storage, to maintain an inward concentration gradient of retinol (15). Interestingly, retinol uptake by STRA6 was found to trigger the activation of a signaling cascade mediated by tyrosine kinases known as Janus kinases (JAK) and associated transcription factors (STAT). JAK/STAT signaling pathway regulates the expression of a wide range of cytokines, hormones, and growth factors (16). Animal studies have reported that an increased expression of genes, such as *SOCS3* by the JAK/STAT pathway, could result in the inhibition of insulin signaling. Hence, obese mice lacking LRAT or STRA6 appear to be protected from retinol/STRA6-induced insulin resistance (17, 18).

Regulatory capacity of retinal

Apart from its role as a ligand for opsin in the visual cascade (see Visual system and eyesight), retinal has been specifically implicated in the regulation of genes important for lipid metabolism. In humans, two types of adipose tissue have been distinguished based on their respective functions: white adipose tissue (WAT) stores fatty acids as triglycerides, and brown adipose tissue (BAT) oxidizes fatty acids to generate heat (thermogenesis). In the mitochondrial respiratory chain of brown adipose cells, the processes of electron transport and ATP production are uncoupled (dissociated) to permit the rapid production of heat from fatty acid oxidation (19).

Retinaldehyde dehydrogenase 1 (RALDH1), which converts retinal to retinoic acid, is highly expressed in WAT but not in BAT. The suppression of RALDH1 expression in WAT can induce a thermogenic phenotype resembling that of BAT (20). During adipocyte differentiation, the stimulation of cells with all-*trans* retinal has been found to activate the *UCP1* gene required for thermogenesis while inhibiting genes promoting adipogenesis, such as *PPARγ* (20). Retinal also appeared to regulate lipid metabolism and adiposity in bone marrow by inhibiting PPARγ/RXR heterodimer-mediated gene expression (21). In addition, retinal was found to inhibit gluconeogenic gene expression and glucose production in the liver of mice deficient in RALDH1 (22).

Immunity

Vitamin A was initially coined "the anti-infective vitamin" because of its importance in the normal functioning of the immune system (23). The skin and mucosal cells, lining the airways, digestive tract, and urinary tract function as a barrier and form the body's first line of defense against infection. Retinoic acid (RA) is produced by antigen-presenting cells (APCs), including macrophages and dendritic cells, found in these mucosal interfaces and associated lymph nodes. RA appears to act on dendritic cells themselves to regulate their differentiation, migration, and antigen-presenting capacity. In addition, the production of RA by APCs is required for the differentiation of naïve CD4 T-lymphocytes into induced regulatory T- lymphocytes (Tregs). Critical to the maintenance of mucosal integrity, the differentiation of Tregs is driven by all-*trans*-RA through RARα-mediated regulation of gene expression (see Regulation of gene expression). Also, during inflammation, all-*trans*-RA/RARα signaling pathway promotes the conversion of naïve CD4 T-lymphocytes into effector T-lymphocytes – type 1 helper T-cells (Th1) – (rather than into Tregs) and induces the production of proinflammatory cytokines by effector T-lymphocytes in response to infection. There is also substantial evidence to suggest that RA may help prevent the development of autoimmunity (reviewed in 24).

Prenatal and postnatal development

Both vitamin A excess and deficiency are known to cause birth defects. Retinoid signaling begins soon after the early phase of embryonic development known as gastrulation. During fetal development, RA is critical for the development of organs, including the heart, eyes, ears, lungs, as well as other limbs and visceral organs. Vitamin A has been implicated in fetal lung maturation (2). Vitamin A status is lower in preterm newborns than in full-term infants (25). There is some evidence to suggest that vitamin A supplementation may help reduce the incidence of chronic lung disease and mortality in preterm newborns (see Disease Prevention). Retinoid signaling is also involved in the expression of many proteins of the extracellular matrix (ECM; material surrounding cells), including collagen, laminin, and proteoglycans (26). Vitamin A deficiency may then result in alterations of the ECM composition, thus disrupting organ morphology and function (reviewed in 26).

Red blood cell production (erythropoiesis)

Red blood cells (erythrocytes), like all blood cells, are derived from pluripotent stem cells in the bone marrow. Studies involving *in vitro* culture systems have suggested a role for retinoids in stem cell commitment and differentiation to the red blood cell lineage. Retinoids might also regulate apoptosis (programmed cell death) of red blood cell precursors (erythropoietic progenitor cells) (27). However, whether retinoids regulate erythropoiesis *in vivo* has not been established. Yet, vitamin A supplementation in vitamin A deficient-individuals has been shown to increase hemoglobin concentrations. Additionally, vitamin A appears to facilitate the mobilization of iron from storage sites to the developing red blood cell for incorporation into hemoglobin, the oxygen carrier in red blood cells (27, 28).

Nutrient interactions

Zinc

Zinc deficiency is thought to interfere with vitamin A metabolism in several ways (29): (1) zinc deficiency results in decreased synthesis of retinol-binding protein (RBP), which transports retinol through the circulation to peripheral tissues and protects the organism against potential toxicity of retinol; (2) zinc deficiency results in decreased activity of the enzyme that releases retinol from its storage form, retinyl palmitate, in the liver; and (3) zinc is required for the enzyme that converts retinol into retinal (30). The health consequences of zinc deficiency on vitamin A nutritional status in humans are yet to be defined (29).

Iron

Vitamin A deficiency often coexists with iron deficiency and may exacerbate iron deficiency anemia by altering iron metabolism (27). Vitamin A supplementation has beneficial effects on iron deficiency anemia and improves iron nutritional status among children and pregnant women (27, 28). The combination of supplemental vitamin A and iron seems to reduce anemia more effectively than either supplemental iron or vitamin A alone (31). Moreover, studies in rats have shown that iron deficiency alters plasma and liver levels of vitamin A (32, 33).

Deficiency

Vitamin A deficiency usually results from inadequate intakes of vitamin A from animal products (as preformed vitamin A) and fruit and vegetables (as provitamin A carotenoids). In developing countries, vitamin A deficiency and associated disorders predominantly affect children and women of reproductive age. Other individuals at risk of vitamin A deficiency are those with poor absorption of lipids due to impaired pancreatic or biliary secretion and those with inflammatory bowel diseases, such as Crohn's disease and celiac disease (2). Subclinical vitamin A deficiency is often defined by serum retinol concentrations lower than 0.70 μmol/L (20 μg/dL). In severe vitamin A deficiency, vitamin A body stores are depleted and serum retinol concentrations fall below 0.35 μmol/L (10 μg/dL). Other biomarkers have been calibrated to assess vitamin A nutritional status (reviewed in 34). Of note, the World Health Organization considers vitamin A deficiency a public health problem when the prevalence of low serum retinol (<0.70 μmol/L) reaches 15% or more of a defined population.

Vitamin A deficiency-related disorders

Disease of the eye and blindness

With an estimated 250,000 to 500,000 children becoming blind annually, vitamin A deficiency constitutes the leading preventable cause of blindness in low- and middle-income nations (35). The earliest symptom of vitamin A deficiency is impaired dark adaptation known as night blindness or nyctalopia. The next clinical stage is the occurrence of abnormal changes in the conjunctiva (corner of the eye), manifested by the presence of Bitot's spots. Severe or prolonged vitamin A deficiency eventually results in a condition called xerophthalmia (Greek for dry eye), characterized by changes in the cells of the cornea (clear covering of the eye) that ultimately result in corneal ulcers, scarring, and blindness (36). Immediate administration of 200,000 international units (IU) of vitamin A for two consecutive days is required to prevent blinding xerophthalmia (36).

There is an estimated 19.1 million pregnant women worldwide (especially in Sub-Saharan Africa, Southeast Asia, and Central America) with vitamin A deficiency and over half of them are affected by night blindness (37). The prevalence of vitamin A deficiency and night blindness is especially high during the third trimester of pregnancy due to accelerated fetal growth. Also, approximately 190 million preschool-age children have low serum retinol concentrations (<0.70 μmol/L), with 5.2 million suffering from night blindness. Moreover, half of the children affected by severe vitamin A deficiency-induced blinding xerophthalmia are estimated to die within a year of becoming blind (37). The World Health Organization (WHO) and the United Nations Children's Fund (UNICEF) promote vitamin A supplementation as a public health intervention to reduce child mortality in areas and populations where vitamin A deficiency is prevalent (38-40).

Susceptibility to infectious diseases

Infectious diseases have been associated with depletion of vitamin A hepatic reserves (already limited in vitamin A-deficient subjects), reduced serum retinol concentrations, and increased loss of vitamin A in the urine (37). Infection with the measles virus was found to precipitate conjunctival and corneal damage, leading to blindness in children with poor vitamin A status (41). Conversely, vitamin A deficiency can be considered a nutritionally acquired immunodeficiency disease (42). Even children who are only mildly deficient in vitamin A have a higher incidence of respiratory complications and diarrhea, as well as a higher rate of mortality from measles infection compared to children consuming sufficient vitamin A (43). Because vitamin A supplementation may decrease both the severity and incidence of measles complications in developing countries (see Disease Prevention), WHO recommends that children aged at least one year receive 200,000 IU of vitamin A (60 mg RAE) for two consecutive days in addition to standard treatment when they are infected with measles virus and live in areas of vitamin A deficiency (44).

A recent prospective cohort study, conducted in 2,774 Colombian children (ages, 5-12 years old) followed for a median 128 days, also reported an inverse relationship between plasma retinol concentrations and rates of diarrhea with vomiting and cough with fever, the latter being a strong predictor of influenza infection (flu) (45). A review of five randomized, placebo-controlled studies that included 7,528 HIV-positive pregnant or breast-feeding women found no substantial benefit of vitamin A supplementation in reducing the mother-to-child transmission of HIV (46). One early observational study found that HIV-infected women who were vitamin A deficient were three to four times more likely to transmit HIV to their infants (47). Yet, no trial to date has provided any information on potential adverse effects of vitamin A supplementation on mother-to-child HIV transmission (48).

Thyroid dysfunction

In North and West Africa, vitamin A deficiency and iodine deficiency induced-goiter can coexist in up to 50% of children. The response to iodine prophylaxis in iodine-deficient populations appears to depend on various nutritional factors, including vitamin A status (49, 50). Vitamin A deficiency in animal models was found to interfere with the pituitary-thyroid axis by (1) increasing the synthesis and secretion of thyroid-stimulating hormone (TSH) by the pituitary gland, (2) increasing the size of the thyroid gland, (3) reducing iodine uptake by the thyroid gland and impairing the synthesis and iodination of thyroglobulin, and (4) increasing circulating concentrations of thyroid hormones (reviewed in 51). A cross-sectional study of 138 children with concurrent vitamin A and iodine deficiencies found that the severity of vitamin A deficiency was associated with higher risk of goiter and higher concentrations of circulating TSH and thyroid hormones (50). These children received iodine-enriched salt with either vitamin A (200,000 IU at baseline and 5 months) or placebo in a randomized, double-blind, 10-month trial. This vitamin A supplementation significantly decreased TSH concentration and thyroid volume compared to placebo (50). In another trial, supplementation of vitamin A to iodine-deficient children had no additional effect to iodine on thyroid status compared to placebo, but vitamin A supplementation alone (without iodine) reduced the volume of the thyroid gland, as well as TSH and thyroglobulin concentrations (52).

Other disorders

Phrynoderma or follicular hyperkeratosis is a skin condition characterized by an excessive production of keratin in hair follicles. The lesions first appear on the extremities, shoulders, and buttocks and may spread over the entire body in the severest cases (53). While vitamin A deficiency may contribute to the occurrence of phrynoderma, the condition has been strongly associated with multiple nutritional deficiencies and is considered a sign of general malnutrition. A rare case of esophagitis (inflammation of the esophagus) has recently been attributed to hyperkeratosis secondary to vitamin A deficiency (54).

Also, vitamin A deficiency affects iron mobilization, impairs hemoglobin synthesis, and precipitates iron deficiency anemia that is only alleviated with supplementation of both vitamin A and iron (see Nutrient interactions) (27).

The Recommended Dietary Allowance (RDA)

Retinol Activity Equivalents (RAE)

Vitamin A can be obtained from food as preformed vitamin A in animal products or as provitamin A carotenoids in fruit and vegetables (see Food sources). Yet, while preformed vitamin A is effectively absorbed, stored, and hydrolyzed to form retinol, provitamin A carotenoids like β-carotene are less easily digested and absorbed, and must be converted to retinol and other retinoids by the body after uptake into the small intestine. The efficiency of conversion of provitamin A carotenes into retinol is highly variable, depending on factors such as food matrix, food preparation, and one's digestive and absorptive capacities (55).

The most recent international standard of measure for vitamin A is retinol activity equivalents (RAE), which represent vitamin A activity as retinol. It has been determined that 2 micrograms (μg) of β-carotene in oil provided as a supplement could be converted by the body to 1 μg of retinol giving it an RAE ratio of 2:1. However, 12 μg of β-carotene from food are required to provide the body with 1 μg of retinol, giving dietary β-carotene an RAE ratio of 12:1. Other provitamin A carotenoids in food are less easily absorbed than β-carotene, resulting in RAE ratios of 24:1. RAE ratios are shown in **Table 1** (56).

Table 1. Retinol activity equivalents (RAE) Ratios for Preformed Vitamin A and Provitamin A Carotenoids

Quantity Consumed	Quantity Bioconverted to Retinol	RAE Ratio
1 μg of dietary or supplemental vitamin A	1 μg of retinol*	1:1
2 μg of supplemental β-carotene	1 μg of retinol	2:1
12 μg of dietary β-carotene	1 μg of retinol	12:1
24 μg of dietary α-carotene	1 μg of retinol	24:1
24 μg of dietary β-cryptoxanthin	1 μg of retinol	24:1

*1 IU is equivalent to 0.3 microgram (μg) of retinol, and 1 μg of retinol is equivalent to 3.33 IU of retinol.

Determination of the RDA

The RDA for vitamin A was revised by the Food and Nutrition Board (FNB) of the US Institute of Medicine (IOM) in 2001. The RDA is based on the Estimated Average Requirement (EAR), which is defined as the biological requirement for 50% of the population. The RDA is the recommended intake needed by nearly all of the population to ensure adequate hepatic stores of vitamin A in the body (20 μg/g for four months if the person consumes a vitamin A-deficient diet) to support normal reproductive function, immune function, gene expression, and vision (for details of calculations, see 56). **Table 2** lists the RDA values in micrograms (μg) of Retinol Activity Equivalents (RAE) per day.

Table 2. Recommended Dietary Allowance (RDA) for Vitamin A as Preformed Vitamin A (micrograms [μg] of Retinol Activity Equivalents [RAE]/day)

Life Stage	Age	Males (μg/day)	Females (μg/day)
Infants	0-6 months	400 (AI)	400 (AI)
Infants	7-12 months	500 (AI)	500 (AI)
Children	1-3 years	300	300
Children	4-8 years	400	400
Children	9-13 years	600	600
Adolescents	14-18 years	900	700
Adults	19 years and older	900	700
Pregnancy	18 years and younger	-	750
Pregnancy	19 years and older	-	770
Breast-feeding	18 years and younger	-	1,200
Breast-feeding	19 years and older	-	1,300

Disease Prevention

Bronchopulmonary dysplasia in preterm infants

Preterm infants are born with inadequate body stores of vitamin A, placing them at risk of developing diseases of the eye and the respiratory and gastrointestinal tracts. About one-third of preterm infants born between 22 and 28 weeks of gestation develop bronchopulmonary dysplasia (BPD), a chronic lung disease that can be fatal or result in life-long morbidities in survivors. A few randomized controlled studies have investigated the effect of postnatal vitamin A supplementation on the incidence of BPD and the risk of mortality in very low birth weight infants (≤1,500 g) requiring respiratory support (57-59). In the largest, multicenter, randomized, blinded, placebo-controlled trial that enrolled 807 extremely low birth weight (ELBW; ≤1,000 g) preterm newborns, the intramuscular administration of 5,000 IU of vitamin A three times a week for four weeks significantly, though modestly, reduced the risk of BPD or death at 36 weeks' postmenstrual age (gestational age plus chronological age) (58). While vitamin A supplementation was included in some neonatal programs after this trial (60), a national shortage in vitamin A supply that has affected US neonatal intensive care units since 2010 has led to a significant reduction in the use of vitamin A supplementation in premature newborns (401-1,000 g at birth) with respiratory failure (61, 62). However, a retrospective analysis of US nationwide data from 6,210 preterm infants born between 2010 and 2012 found that a reduction in vitamin A prophylaxis from 27.2% to 2.1% during the same period had no significant impact on the incidence of BPD or death before hospital discharge (62).

In another retrospective study, the nonrandomized use of vitamin A supplementation with inhaled nitric oxide (iNO) was found to result in a lower incidence of BPD (but not mortality) compared to iNO therapy alone in preterm newborns with a birth weight of 750-999 g (63). Neurodevelopment index scores at one year of age were also improved in the vitamin A group of newborns weighing 500-749 g at birth. Yet, caution is advised with the interpretation of the results, especially because the trial was not designed to assess the effect of vitamin A. In Germany, one large, multicenter, randomized study – the NeoVitaA trial – is under way to explore the effect of high-dose oral vitamin A (5,000 IU/kg/day) for 28 days on the incidence of BPD and mortality at 36 weeks' postmenstrual age (64).

While high doses of vitamin A during early pregnancy can cause birth defects (see Safety), vitamin A supplementation during late pregnancy may improve maternal and fetal vitamin A status (65). Although a few randomized controlled trials have failed to show an effect on maternal and neonatal mortality (66), more research is required to assess whether vitamin A supplementation during pregnancy reduces BPD incidence in infants.

Childhood morbidity and mortality

A recent meta-analysis of randomized controlled trials evaluating the preventive effect of vitamin A on childhood mortality indicated that vitamin A supplementation (200,000 IU every 4 or 6 months) reduced all-cause mortality by 25% (13 studies) and diarrhea-specific mortality by 30% (7 studies) in children aged 6 to 59 months. However, vitamin A administration in this age group had no preventive effect on rates of pneumonia-specific mortality (7 studies), measles-specific mortality (5 studies), or meningitis-specific mortality (3 studies). Moreover, no reduction in the risk of disease-specific mortality was found in neonates (0 to 28 days of age) and infants 1 to 6 months of age supplemented with vitamin A (67). Another meta-analysis of randomized controlled trials found no evidence of a reduction in mortality risk during infancy when either breast-feeding mothers (7 studies) or infants aged less than six months (9 studies) were supplemented with vitamin A (68).

Current WHO policy recommends vitamin A supplementation at routine vaccination contacts in children after six months of age living in regions at high risk of vitamin A deficiency. Supplementation with high doses of vitamin A – 100,000 IU (30 mg RAE) for infants 6 to 11 months of age and 200,000 IU (60 mg RAE) for children 12 to 59 months of age – is thought to provide adequate protection for up to six months (38). A recent placebo-controlled trial in Guinea-Bissau, which randomized 7,587 children (ages, 6 to 23 months old) to receive vitamin A supplementation at one vaccination contact, evaluated the co-administration of vitamin A and vaccines on child mortality (69). The study found that vitamin A supplementation had no effect on overall mortality rates, although a six-month follow-up of infants given both measles and DTP (diphtheria-tetanus-pertussis) vaccinations showed a significant reduction in mortality in girls, but not in boys (69). Although neonatal vitamin A supplementation is not currently recommended, a trial assessing the benefit of early measles vaccination – at 4.5 rather than the usual 9 months of age – found no reduction in mortality rates when children had received neonatal vitamin A supplementation (70). The recent pooled analysis of previous trials of vitamin A supplementation (VITA I-III) in Guinea-Bissau confirmed that vitamin A supplementation may interfere with vaccines. Specifically, compared to placebo, neonatal vitamin A supplementation was associated with a significant increase in mortality rates in boys (but not in girls) when children had received measles virus vaccination at 4.5 months of age rather than the usual 9 months of age (71). The timing of vitamin A interventions needs to be further examined in relation to the timing of vaccinations in order to maximize their benefits.

Complications from measles infection

An earlier meta-analysis of seven randomized controlled trials examining specifically the role of vitamin A supplementation in 2,069 children with measles found no overall reduction on the risk of mortality (72). Yet, the pooled analysis of four studies that reported the age distribution of participants found an 83% lower risk of mortality with two doses of 200,000 IU of vitamin A in children younger than two years. In addition, the pooled analysis of three studies indicated a 67% reduction in the risk of pneumonia-led mortality (72). Similar to WHO and UNICEF guidelines, the American Academy of Pediatrics recommends vitamin A supplementation for children over six months of age when they are infected with measles while malnourished, immunodeficient, or are at risk of measles complications or vitamin A deficiency disorders (73). Although measles infection has been associated with vitamin A deficiency and blindness, there is currently no evidence to suggest that vitamin A supplementation reduces the risk of blindness in children infected with measles (74).

Cancer

Studies in cell culture and animal models have documented the capacity for natural and synthetic retinoids to reduce carcinogenesis significantly in skin, breast, liver, colon, prostate, and other sites. However, the results of human studies examining the relationship between the consumption of preformed vitamin A and cancer do not currently suggest that consuming vitamin A at intakes greater than the RDA benefit in the prevention of cancer (2).

Lung cancer

The results of the β-Carotene And Retinol Efficacy Trial (CARET) have suggested that high-dose supplementation of preformed vitamin A and β-carotene should be avoided in people at high risk for lung cancer (75). In the CARET study, about 9,000 people (smokers and people with asbestos exposure) were assigned a daily regimen of 25,000 IU (7,500 μg RAE) of retinyl palmitate and 30 mg of β-carotene, while a similar number of people were assigned a placebo. After four years of follow-up, the incidence of lung cancer was 28% higher in the supplemented group compared to the placebo group; however, the incidence was not different six years after the intervention ended (76). A possible explanation for an increase in lung cancer is that the oxidative environment of the lung, created by smoke or asbestos exposure, could give rise to unusual carotenoid cleavage products, which might promote carcinogenesis (77). Interestingly, a case-control study that included 749 lung cancer cases and 679 controls from the CARET trial found a significant association between lung cancer risk reduction and high vitamin D intakes (≥400 IU/day) in individuals who received the active CARET supplements or in those with vitamin A intakes equal to or greater than 1,500 μg RAE/day (78). Further, a recent meta-analysis of four randomized controlled trials, including a total of 202,924 participants at low risk of lung cancer, indicated that supplementation with retinol and/or β-carotene had no significant effect on lung cancer incidence (79). At present, it seems unlikely that increased intake of preformed vitamin A (e.g., retinol) could lower the risk of lung cancer.

Disease Treatment

Retinoids may be used at pharmacological doses to treat several conditions, including, acute promyelocytic leukemia, retinitis pigmentosa, and various skin diseases. It is important to note that treatment with high doses of natural or synthetic retinoids overrides the body's own control mechanisms; therefore, retinoid therapies are associated with potential side effects and toxicities. Additionally, all of the retinoid compounds have been found to cause fetal deformations. Thus, women who have a chance of becoming pregnant should avoid treatment with these medications. Retinoids tend to be very long acting: side effects and birth defects have been reported to occur months after discontinuing retinoid therapy (2). The retinoids discussed below are prescription drugs and should not be used without medical supervision.

Acute promyelocytic leukemia

Normal differentiation of myeloid stem cells in the bone marrow gives rise to platelets, red blood cells, and white blood cells (also called leukocytes) that are important for the immune response. Altered differentiation of myeloid cells can result in the proliferation of immature white blood cells, giving rise to leukemia. Reciprocal chromosome translocations involving the promyelocytic leukemia (PML) gene and the gene coding for retinoic acid receptor α (RARα) lead to a specific type of leukemia called acute promyelocytic leukemia (APL). The fusion protein PML/RARα represses transcription by binding to RARE in the promoter of retinoid-responsive genes involved in hematopoietic cell differentiation. Gene repression by PML/RARα is achieved by the recruitment of several chromatin modifiers, including histone deacetylases (HDACs) and DNA methyltransferases (DNMTs). Contrary to RARα wild-type receptor, PML/RARα appears to be insensitive to physiological concentrations of retinoic acid (RA) such that only treatments with high doses of all-*trans*-RA can restore normal differentiation and lead to significant improvements and complete remission in some APL patients (80).

More information on APL treatment programs can be found in the National Cancer Institute website.

Diseases of the skin

Both natural and synthetic retinoids have been used as pharmacologic agents to treat disorders of the skin. Acitretin is a synthetic retinoid that has been proven useful in combination treatments for psoriasis (81). Topical tretinoin (all-*trans*-retinoic acid) and oral isotretinoin (13-*cis*-retinoic acid) have been used successfully to treat mild-to-severe acne vulgaris (82, 83). Retinoids exhibit anti-inflammatory properties and regulate the proliferation and differentiation of skin epithelial cells, as well as the production of sebum. Use of pharmacological doses of retinoids (especially oral isotretinoin) by pregnant women causes birth defects and is therefore contraindicated prior to and during pregnancy (see Safety in pregnancy).

For more information on the use of retinoids in the management of acne, see the article on Vitamin A and Skin Health.

Retinitis pigmentosa

Retinitis pigmentosa (RP) affects approximately 1.5 million people worldwide and is a leading cause of inherited blindness. RP describes a broad spectrum of genetic disorders that result in the progressive loss of photoreceptor cells (rods and cones) in the retina of the eye (84). While at least 45 loci have been associated with RP, mutations in the rhodopsin gene (*RHO*), the usherin gene (*USH2A*), and the RP GTPase regulator gene (*RPGR*) account for about 30% of all RP cases (85).

Early symptoms of RP include impaired dark adaptation and night blindness, followed by the progressive loss of peripheral and central vision over time (85). The results of only one randomized controlled trial in 601 patients with common forms of RP indicated that supplementation with 15,000 IU/day of retinyl palmitate (4,500 μg RAE) significantly slowed the loss of retinal function over a period of four to six years (86). In contrast, supplementation with 400 IU/day of vitamin E (*dl*-α-tocopherol) modestly but significantly increased the loss of retinal function, suggesting that patients with common forms of RP may benefit from long-term vitamin A supplementation but should avoid high-dose vitamin E supplementation. Up to 12 years of follow-up in these patients did not reveal any signs of liver toxicity as a result of excess vitamin A intake (87). Because neither children younger than 18 years nor adults affected by less common forms of RP were included in the trial, no formal recommendation about vitamins A and E could be made (85). High-dose vitamin A supplementation to slow the course of RP requires medical supervision and must be discontinued if there is a possibility of pregnancy (see Safety).

Sources

Food sources

Free retinol is not generally found in food. Retinyl esters (including retinyl palmitate) are the storage form of retinol in animals and thus the main precursors of retinol in food from animals. Plants contain carotenoids, some of which are precursors for vitamin A (e.g., α-carotene, β-carotene, and β-cryptoxanthin). Yellow- and orange-colored vegetables contain significant quantities of carotenoids. Green vegetables also contain carotenoids, though yellow-to-red pigments are masked by the green pigment of chlorophyll (1). The table below lists a number of good food sources of vitamin A, including fruit and vegetables, along with their vitamin A content. The retinol activity is indicated in micrograms of retinol activity equivalents (μg RAE). For information on this unit of measurement, see the section on RAE. In addition, use USDA's FoodData Central to check foods for their content of carotenoids without vitamin A activity, such as lycopene, lutein, and zeaxanthin.

Vitamin A international units (IUs)

Vitamin A may still be listed on food and supplement labels in international units versus as μg RAE ('mcg' on labels). USDA's FoodData Central also provides the vitamin A content of food sources using the vitamin A international unit (IU). Yet, contrary to RAE, the number of IUs of vitamin A does not reflect the bioavailability of vitamin A from different food sources. Conversion rates between IUs and μg RAE are set as follows:

- 1 IU of retinol is equivalent to 0.3 μg RAE
- 1 IU of supplemental β-carotene is equivalent to 0.3 μg RAE
- 1 IU of dietary β-carotene is equivalent to 0.05 μg RAE
- 1 IU of α-carotene or β-cryptoxanthin to 0.025 μg RAE

Thus, in **Table 3**, the number of IUs of vitamin A in carotenoid-containing food (numbers in italics) can be obtained by multiplying the RAE by approximately 20.

Table 3. Some Food Sources of Vitamin A

Food	Serving	Preformed Vitamin A (Retinol), μg	Vitamin A, μg RAE	Vitamin A, IU
Beef liver, cooked	1 slice (68 g)	6,421*	6,421*	21,566*
Cod liver oil	1 teaspoon	1,350	1,350	4,500
Fortified breakfast cereal (oats)	1 serving (1 oz)	216	216	721
Egg	1 large	80	80	270
Butter	1 tablespoon	95	95	355
Whole milk	1 cup (8 fl oz)	110	110	395
2% fat milk (vitamin A added)	1 cup (8 fl oz)	134	134	464
Nonfat milk (vitamin A added)	1 cup (8 fl oz)	149	149	500
Sweet potato (canned, mashed)	½ cup	0	555	*11,091*
Sweet potato (baked)	½ cup	0	961	*19,218*
Pumpkin (canned)	½ cup	0	953	*19,065*
Carrot (raw, chopped)	½ cup	0	534	*10,692*
Cantaloupe	½ medium melon	0	466	*9,334*
Mango	1 fruit	0	181	*3,636*
Spinach (cooked)	½ cup	0	472	*9,433*
Broccoli (cooked)	½ cup	0	60	*1,207*
Kale (cooked)	½ cup	0	443	*8,854*
Collards (cooked)	½ cup	0	361	*7,220*
Squash, butternut (cooked)	½ cup	0	572	*11,434*

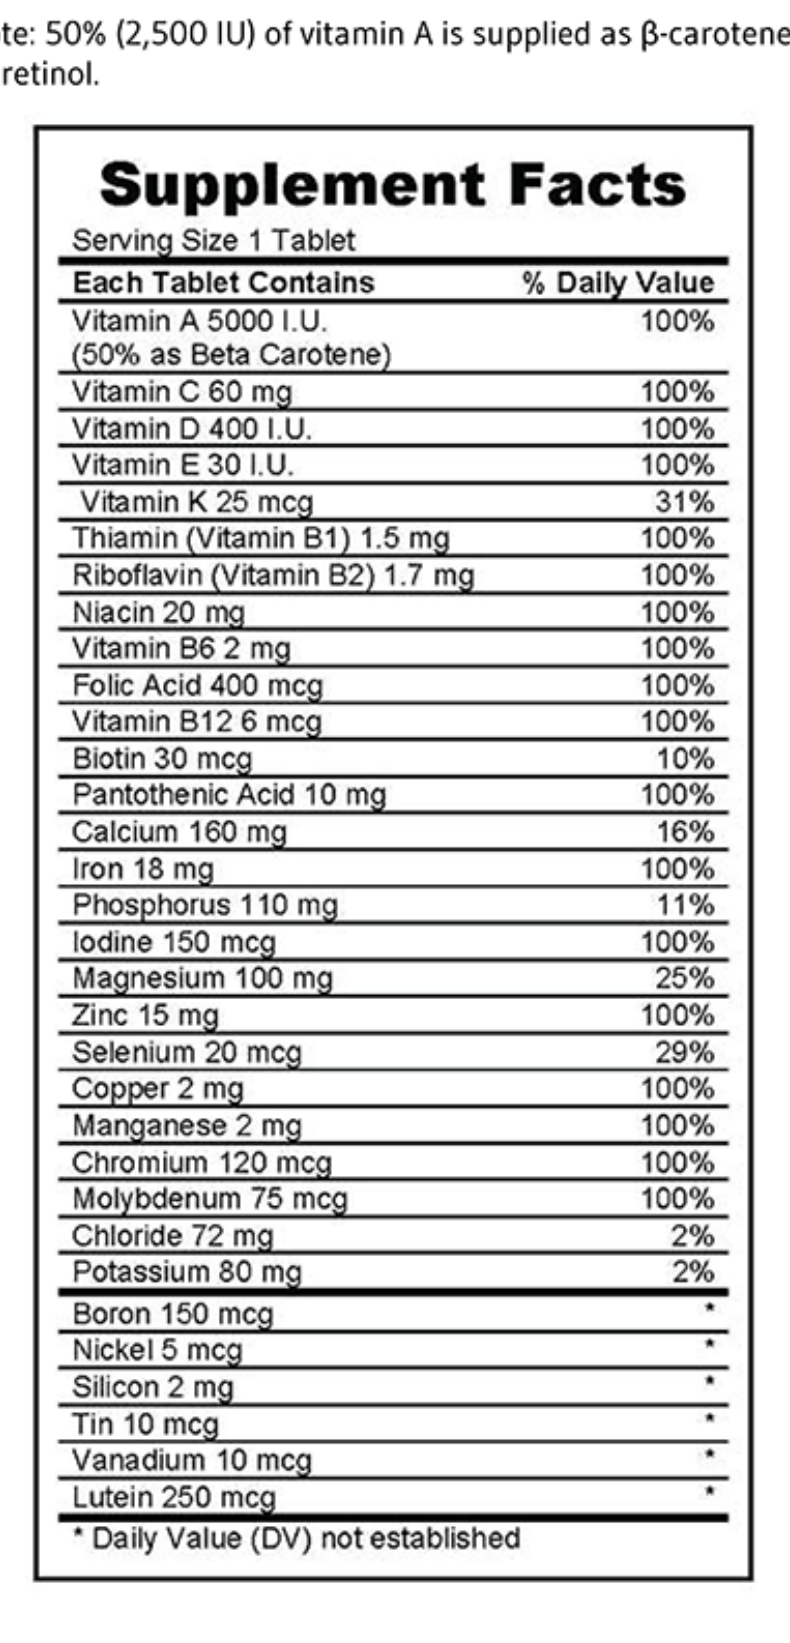
*Above the tolerable upper intake level (UL) of 3,000 μg RAE (10,000 IU)/day

Supplements

The principal forms of preformed vitamin A in supplements are retinyl palmitate and retinyl acetate. β-Carotene is also a common source of vitamin A in supplements, and many supplements provide a combination of retinol and β-carotene (88). If a percentage of the total vitamin A content of a supplement comes from β-carotene, this information is included in the Supplement Facts label under vitamin A (**Figure 4**). Some multivitamin supplements available in the US provide up to 5,000 IU of preformed vitamin A, corresponding to 1,500 μg RAE, which is substantially more than the current RDA for vitamin A. This is due to the fact that the Daily Values (DV) used by the US Food and Drug Administration (FDA) for supplement labeling are based on the RDA established in 1968 rather than the most recent RDA, and multivitamin supplements typically provide 100% of the DV for most nutrients. Because retinol intakes of 5,000 IU/day (1,500 μg RAE) may be associated with an increased risk of osteoporosis in older adults (see Safety), some companies have reduced the retinol content in their multivitamin supplements to 2,500 IU (750 μg RAE).

Figure 4. An Example of a Multivitamin/Mineral Supplement Label

Note: 50% (2,500 IU) of vitamin A is supplied as β-carotene, while the rest (2,500 IU) is supplied as retinol.



Supplement Facts

Serving Size 1 Tablet

Each Tablet Contains	% Daily Value
Vitamin A 5000 I.U. (50% as Beta Carotene)	100%
Vitamin C 60 mg	100%
Vitamin D 400 I.U.	100%
Vitamin E 30 I.U.	100%
Vitamin K 25 mcg	31%
Thiamin (Vitamin B1) 1.5 mg	100%
Riboflavin (Vitamin B2) 1.7 mg	100%
Niacin 20 mg	100%
Vitamin B6 2 mg	100%
Folic Acid 400 mcg	100%
Vitamin B12 6 mcg	100%
Biotin 30 mcg	10%
Pantothenic Acid 10 mg	100%
Calcium 160 mg	16%
Iron 18 mg	100%
Phosphorus 110 mg	11%
Iodine 150 mcg	100%
Magnesium 100 mg	25%
Zinc 15 mg	100%
Selenium 20 mcg	29%
Copper 2 mg	100%
Manganese 2 mg	100%
Chromium 120 mcg	100%
Molybdenum 75 mcg	100%
Chloride 72 mg	2%
Potassium 80 mg	2%
Boron 150 mcg	*
Nickel 5 mcg	*
Silicon 2 mg	*
Tin 10 mcg	*
Vanadium 10 mcg	*
Lutein 250 mcg	*

* Daily Value (DV) not established

Safety

Toxicity

The condition caused by vitamin A toxicity is called hypervitaminosis A. It is caused by overconsumption of preformed vitamin A, not carotenoids. Preformed vitamin A is rapidly absorbed and slowly cleared from the body. Therefore, toxicity from preformed vitamin A may result acutely from high-dose exposure over a short period of time or chronically from a much lower intake (2). Acute vitamin A toxicity is relatively rare, and symptoms include nausea, headache, fatigue, loss of appetite, dizziness, dry skin, desquamation, and cerebral edema. Signs of chronic toxicity include dry itchy skin, desquamation, anorexia, weight loss, headache, cerebral edema, enlarged liver, enlarged spleen, anemia, and bone and joint pain. Also, symptoms of vitamin A toxicity in infants include bulging fontanels. Severe cases of hypervitaminosis A may result in liver damage, hemorrhage, and coma. Generally, signs of toxicity are associated with long-term consumption of vitamin A in excess of 10 times the RDA (8,000-10,000 μg RAE/day or 25,000-33,000 IU/day). However, more research is necessary to determine if subclinical vitamin A toxicity is a concern in certain populations (89). There is evidence that some populations may be more susceptible to toxicity at lower doses, including the elderly, chronic alcohol users, and some people with a genetic predisposition to high cholesterol (90). In January 2001, the Food and Nutrition Board of the US Institute of Medicine set the tolerable upper intake level (UL) of vitamin A intake for adults at 3,000 μg RAE (10,000 IU)/day of preformed vitamin A (56).

Table 4. Tolerable Upper Intake Level (UL) for Preformed Vitamin A

Age Group	μg RAE/day	IU/day*
Infants 0-12 months	600	2,000
Children 1-3 years	600	2,000
Children 4-8 years	900	3,000
Children 9-13 years	1,700	5,667
Adolescents 14-18 years	2,800	9,333
Adults 19 years and older	3,000	10,000

*1 IU of preformed vitamin A is equivalent to 0.3 μg RAE, and 1 μg RAE is equivalent to 3.33 IU of preformed vitamin A

Safety in pregnancy

Although normal fetal development requires sufficient vitamin A intake, consumption of excess preformed vitamin A (such as retinol) during early pregnancy is known to cause birth defects. No increase in the risk of vitamin A-associated birth defects has been observed at doses of preformed vitamin A from supplements below 3,000 μg RAE/day (10,000 IU/day) (56). Of note, in 2011, the World Health Organization (WHO) recommended vitamin A supplementation (up to 3,000 μg RAE/day or 7,500 μg RAE/week) during pregnancy in areas with high prevalence of vitamin A deficiency for the prevention of blindness (91). In industrialized countries, pregnant or potentially pregnant women should monitor their intake of vitamin A from fortified food and food naturally high in preformed vitamin A (e.g., liver) and avoid taking daily multivitamin supplements that contain more than 1,500 μg RAE (5,000 IU) of vitamin A. There is no evidence that consumption of vitamin A from β-carotene might increase the risk of birth defects. The synthetic derivative of retinol, isotretinoin, is known to cause serious birth defects and should not be taken during pregnancy or if there is a possibility of becoming pregnant (82). Tretinoin (all-*trans*-retinoic acid), another retinol derivative, is prescribed as a topical preparation that is applied to the skin. Although percutaneous absorption of topical tretinoin is minimal, its use during pregnancy is not recommended (92).

Do high intakes of vitamin A increase the risk of osteoporosis?

Results from some prospective studies have suggested that long-term intakes of preformed vitamin A in excess of 1,500 μg RAE/day (equivalent to 5,000 IU/day of vitamin A as retinol) were associated with reduced bone mineral density (BMD) and increased risk of osteoporotic fracture in older adults (93-95). However, other investigators failed to observe such detrimental effects on BMD and/or fracture risk (96-98). The recent meta-analysis of four prospective studies, including nearly 183,000 participants over 40 years of age, found that highest vs. lowest quintiles of retinol (preformed vitamin A) intake significantly increased the risk of hip fracture (99). Only excess intakes of retinol, not β-carotene, were associated with adverse effects on bone health. Besides, the pooled analysis of four observational studies also indicated that a U-shaped relationship between circulating retinol and risk of hip fracture, suggesting that both elevated and reduced retinol concentrations in the blood were associated with an increased risk of hip fracture (99).

To date, limited experimental data have suggested that vitamin A (as all-*trans*-retinoic acid) may affect the development of bone-remodeling cells and stimulate bone matrix degradation (resorption) (reviewed in 100). Vitamin A may also interfere with the ability of vitamin D to maintain calcium balance (101). In the large Women's Health Initiative (WHI) prospective study, the highest vs. lowest quintile of retinol intake (≥1,426 μg/day vs. <474 μg/day) was found to be significantly associated with increased risk of fracture only in women with the lowest vitamin D intakes (≤440 IU/day) (102).

Until supplements and fortified food are reformulated to reflect the current RDA for vitamin A, it is advisable for older individuals to consume multivitamin supplements that contain no more than 2,500 IU (750 μg) of preformed vitamin A (usually labeled vitamin A acetate or vitamin A palmitate) and no more than 2,500 IU of additional vitamin A as β-carotene.

Drug interactions

Chronic alcohol consumption results in depletion of liver stores of vitamin A and may contribute to alcohol-induced liver damage (cirrhosis) (103). However, the liver toxicity of preformed vitamin A (retinol) is enhanced by chronic alcohol consumption, thus narrowing the therapeutic window for vitamin A supplementation in alcoholics (103). Oral contraceptives that contain estrogen and progestin increase retinol binding protein (RBP) synthesis by the liver, increasing the export of all-*trans*-retinol/RBP complex to the circulation. Whether this increases the dietary requirement of vitamin A is not known. Also, the use of cholesterol-lowering medications (like cholestyramine and colestipol), as well as orlistat, mineral oil, and the fat substitute, olestra, which interfere with fat absorption, may affect the absorption of fat-soluble vitamins, including vitamin A (88). Further, intake of large doses of vitamin A may decrease the absorption of vitamin K. Retinoids or retinoid analogs, including acitretin, all-*trans*-retinoic acid, bexarotene, etretinate, and isotretinoin, should not be used in combination with single-nutrient vitamin A supplements, because they may increase the risk of vitamin A toxicity (88).

Linus Pauling Institute Recommendation

The RDA for vitamin A (700 μg RAE/day for women and 900 μg RAE/day for men) is sufficient to support normal gene expression, immune function, and vision. However, following the Linus Pauling Institute's recommendation to take a multivitamin/mineral supplement daily could supply as much as 5,000 IU (1,500 μg RAE)/day of vitamin A as retinol, the amount that has been associated with adverse effects on bone health in older adults. For this reason, we recommend taking a multivitamin/mineral supplement that provides no more than 2,500 IU (750 μg) of preformed vitamin A (usually labeled vitamin A acetate or vitamin A palmitate) and no more than 2,500 IU of additional vitamin A as β-carotene. High potency vitamin A supplements should not be used without medical supervision due to the risk of toxicity.

Older adults (>50 years)

Presently, there is little evidence that the requirement for vitamin A in older adults differs from that of younger adults. Additionally, vitamin A toxicity may occur at lower doses in older adults than in younger adults. Further, data from observational studies suggested an association between intakes of preformed vitamin A in excess of 1,500 μg RAE (5,000 IU)/day and increased risk of hip fracture in older people (see Safety). Yet, following the Linus Pauling Institute's recommendation to take a multivitamin/mineral supplement daily could supply as much as 5,000 IU/day of retinol, the amount that has been associated with adverse effects on bone health in older adults. For this reason, we recommend taking a multivitamin/mineral supplement that provides (750 μg) of preformed vitamin A (usually labeled vitamin A acetate or vitamin A palmitate) and no more than 2,500 IU of additional vitamin A as β-carotene. As for all age groups, high potency vitamin A supplements should not be used without medical supervision due to the risk of toxicity.

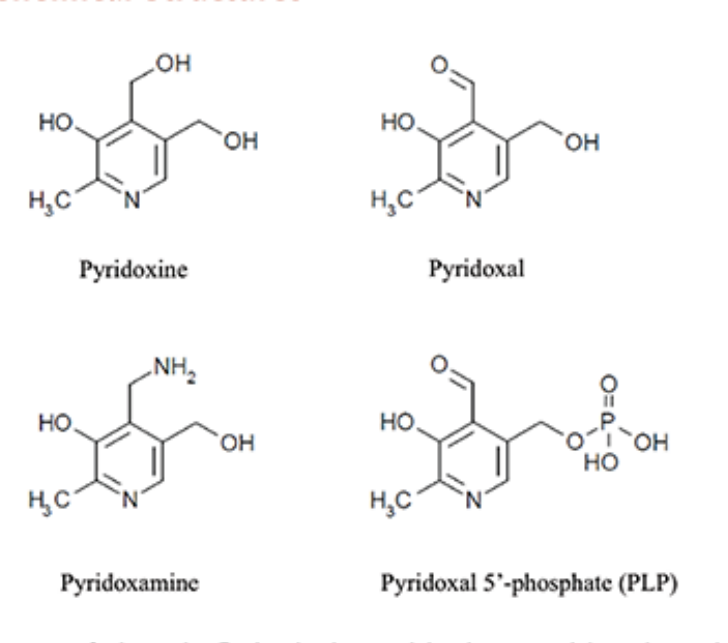
Summary

- Vitamin B_6 and its derivative pyridoxal 5'-phosphate (PLP) are essential to over 100 enzymes mostly involved in protein metabolism. *(More information)*
- High levels of circulating homocysteine are associated with an increased risk of cardiovascular disease. Randomized controlled trials have demonstrated that supplementation with B vitamins, including vitamin B_6, could effectively reduce homocysteine levels. However, homocysteine lowering by B vitamins has failed to lower the risk of adverse cardiovascular outcomes in high-risk individuals. *(More information)*
- Growing evidence from experimental and clinical studies suggests that systemic inflammation underlying most chronic diseases may impair vitamin B_6 metabolism. *(More information)*
- Although supplementation with vitamin B_6 and other B vitamins has not been associated with improved cognitive performance or delayed cognitive deterioration in the elderly, recent studies suggest that vitamin B_6 might help reduce the risk of late-life depression. *(More information)*
- Pharmacologic doses of vitamin B_6 are used to treat seizures in rare inborn errors of vitamin B_6 metabolism. Also, randomized controlled trials support the use of vitamin B_6 to treat morning sickness in pregnant women and suggest a possible benefit in the management of premenstrual syndrome and carpal tunnel syndrome. *(More information)*
- Vitamin B_6 is found in a variety of foods, including fish, poultry, nuts, legumes, potatoes, and bananas. *(More information)*
- Several medications, including anti-tuberculosis drugs, anti-parkinsonians, nonsteroidal anti-inflammatory drugs, and oral contraceptives, may interfere with vitamin B_6 metabolism. *(More information)*

Vitamin B_6 is a water-soluble vitamin that was first isolated in the 1930s. The term vitamin B_6 refers to six common forms, namely pyridoxal, pyridoxine (pyridoxol), pyridoxamine, and their phosphorylated forms. The phosphate ester derivative pyridoxal 5'-phosphate (PLP) is the bioactive coenzyme form involved in over 4% of all enzymatic reactions (**Figure 1**) (1-3).

Figure 1. Vitamin B_6 Chemical Structures



Non-phosphorylated forms of vitamin B_6 include pyridoxine, pyridoxal, and pyridoxamine. While all three of these variants can be phosphorylated, the phosphate ester derivative of pyridoxal, pyridoxal 5'-phosphate (PLP), is the cofactor of most vitamin B_6-dependent enzymes in the body.

Function

Vitamin B_6 must be obtained from the diet because humans cannot synthesize it. PLP plays a vital role in the function of over 100 enzymes that catalyze essential chemical reactions in the human body (4). PLP-dependent enzymes have been classified into five structural classes known as Fold Type I-V (5):

- Fold Type I - aspartate aminotransferase family
- Fold Type II - tryptophan synthase family
- Fold Type III - alanine racemase family
- Fold Type IV - D-amino acid aminotransferase family
- Fold Type V - glycogen phosphorylase family

The many biochemical reactions catalyzed by PLP-dependent enzymes are involved in essential biological processes, such as hemoglobin and amino acid biosynthesis, as well as fatty acid metabolism. Of note, PLP also functions as a coenzyme for glycogen phosphorylase, an enzyme that catalyzes the release of glucose from stored glycogen. Much of the PLP in the human body is found in muscle bound to glycogen phosphorylase. PLP is also a coenzyme for reactions that generate glucose from amino acids, a process known as gluconeogenesis (6).

Nervous system function

In the brain, the PLP-dependent enzyme aromatic L-amino acid decarboxylase catalyzes the synthesis of two major neurotransmitters: serotonin from the amino acid tryptophan and dopamine from L-3,4-dihydroxyphenylalanine (L-Dopa). Other neurotransmitters, including glycine, D-serine, glutamate, histamine, and γ-aminobutyric acid (GABA), are also synthesized in reactions catalyzed by PLP-dependent enzymes (7).

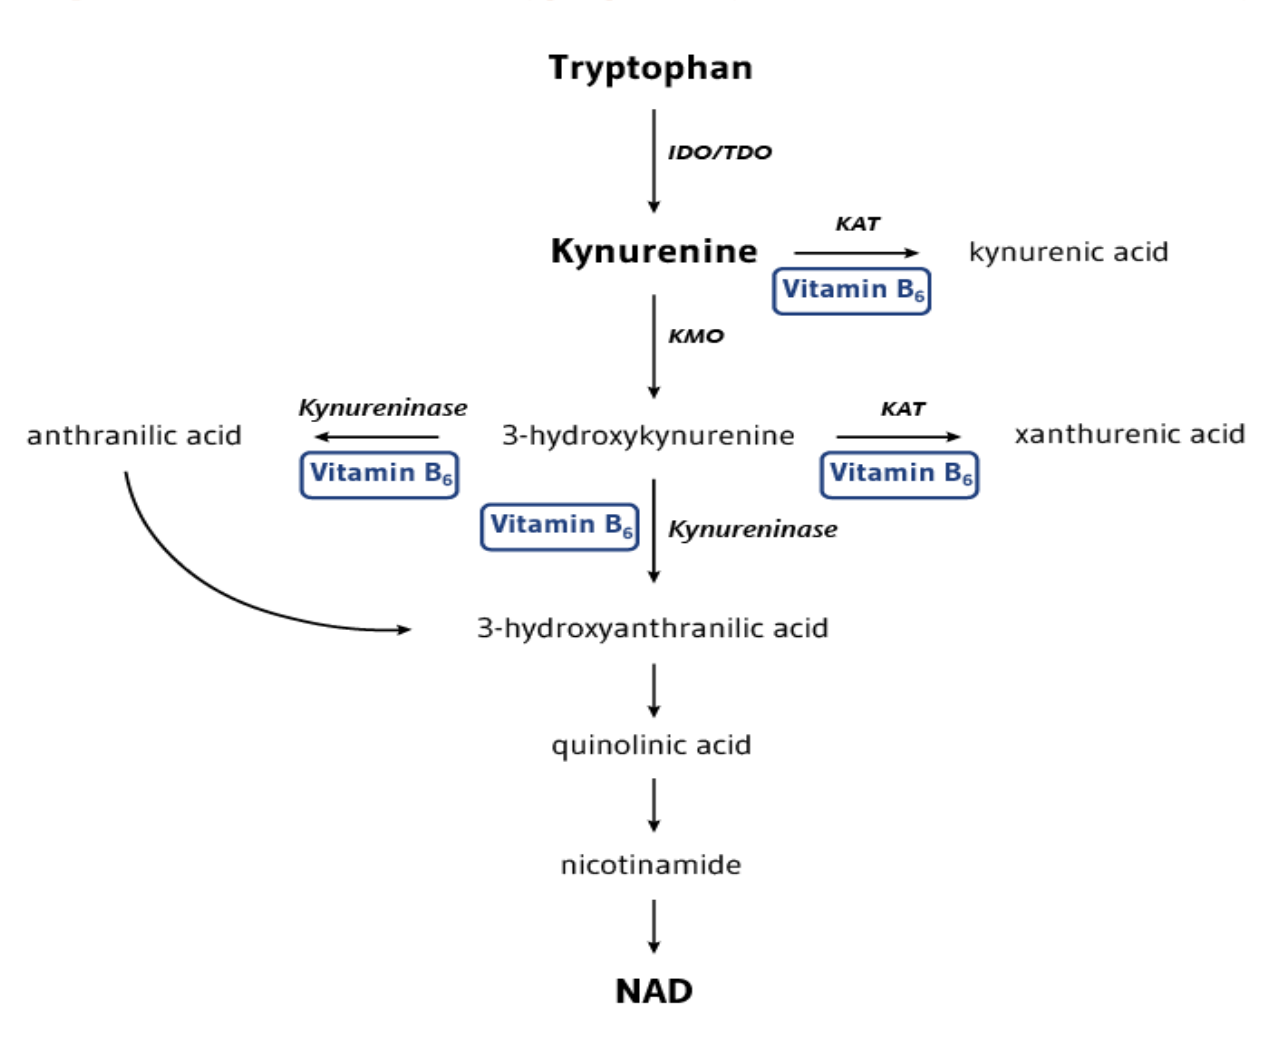
Hemoglobin synthesis and function

PLP functions as a coenzyme of 5-aminolevulinic acid synthase, which is involved in the synthesis of heme, an iron-containing component of hemoglobin. Hemoglobin is found in red blood cells and is critical to their ability to transport oxygen throughout the body. Both pyridoxal and PLP are able to bind to the hemoglobin molecule and affect its ability to pick up and release oxygen. However, the impact of this on normal oxygen delivery to tissues is not known (6, 8). Vitamin B_6 deficiency may impair hemoglobin synthesis and lead to microcytic anemia (3).

Tryptophan metabolism

Deficiency in another B vitamin, niacin, is easily prevented by adequate dietary intakes. The dietary requirement for niacin and the niacin coenzyme, nicotinamide adenine dinucleotide (NAD), can be also met, though to a fairly limited extent, by the catabolism of the essential amino acid tryptophan in the tryptophan-kynurenine pathway (**Figure 2**). Key reactions in this pathway are PLP-dependent; in particular, PLP is the cofactor for the enzyme kynureninase, which catalyzes the conversion of 3-hydroxykynurenine to 3-hydroxyanthranilic acid. A reduction in PLP availability appears to primarily affect kynureninase activity, limiting NAD production and leading to higher concentrations of kynurenine, 3-hydroxykynurenine, and xanthurenic acid in blood and urine (**Figure 2**) (9). Thus, while dietary vitamin B_6 restriction impairs NAD synthesis from tryptophan, adequate PLP levels help maintain NAD formation from tryptophan (10). The effect of vitamin B_6 inadequacy on immune activation and inflammation may be partly related to the role of PLP in the tryptophan-kynurenine metabolism (see Disease Prevention).

Figure 2. Overview of the Tryptophan-Kynurenine Metabolic Pathway



Pyridoxal 5'-phosphate, a vitamin B_6 coenzyme, is required for the activity of key enzymes in the tryptophan catabolic pathway, KAT and kynureninase. Dietary restriction in vitamin B_6 most prominently affects kynureninase activity and results in the shift from 3-hydroxykynurenine metabolism and NAD formation to the production of kynurenic acid and xanthurenic acid. *IDO, indoleamine 2,3-dioxygenase; KAT, kynurenine aminotransferase; KMO, kynurenine 3-monooxygenase; NAD, nicotinamide adenine dinucleotide; TDO, tryptophan 2,3-dioxygenase*

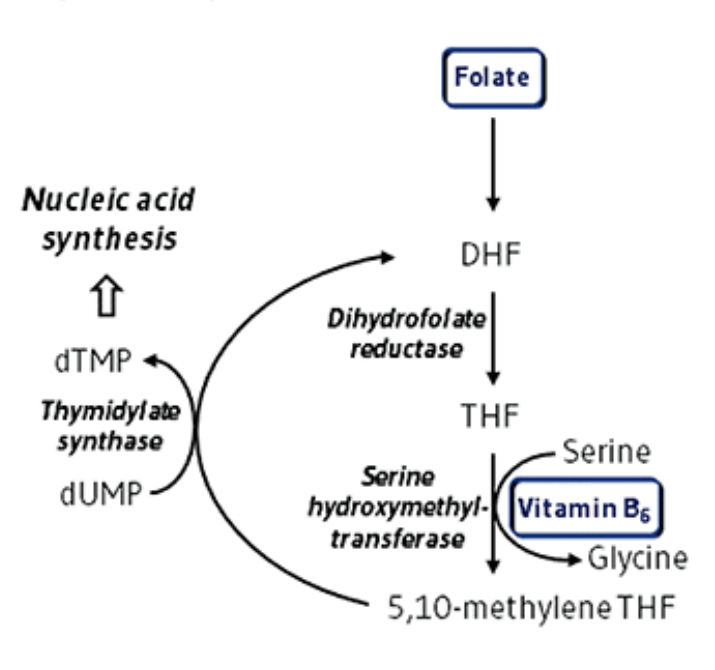
Hormone function

Steroid hormones, such as estrogen and testosterone, exert their effects in the body by binding to steroid hormone receptors in the nucleus of target cells. The nuclear receptors themselves bind to specific regulatory sequences in DNA and alter the transcription of target genes. Experimental studies have uncovered a mechanism by which PLP may affect the activity of steroid receptors and decrease their effects on gene expression. It was found that PLP could interact with RIP140/NRIP1, a repressor of nuclear receptors known for its role in reproductive biology (11). Yet, additional research is needed to confirm that this interaction can enhance RIP140/NRIP1 repressive activity on steroid receptor-mediated gene expression. If the activity of steroid receptors for estrogen, progesterone, testosterone, or other steroid hormones can be inhibited by PLP, it is possible that vitamin B_6 status may influence one's risk of developing diseases driven by steroid hormones, such as breast and prostate cancers (6).

Nucleic acid synthesis

The synthesis of nucleic acids from precursors thymidine and purines is dependent on folate coenzymes. The *de novo* thymidylate (dTMP) biosynthesis pathway involves three enzymes: dihydrofolate reductase (DHFR), serine hydroxymethyltransferase (SHMT), and thymidylate synthase (TYMS) (**Figure 3**). PLP serves as a coenzyme for SHMT, which catalyzes the simultaneous conversions of serine to glycine and tetrahydrofolate (THF) to 5,10-methylene THF. The latter molecule is the one-carbon donor for the generation of dTMP from deoxyuridine monophosphate (dUMP) by TYMS.

Figure 3. *De Novo* Thymidylate Biosynthesis



Folate coenzymes are essential intermediates in the synthesis of nucleic acid precursors thymidine and purines. Thymidylate biosynthesis pathway involves three enzymes: dihydrofolate reductase, serine hydroxymethyltransferase, and thymidylate synthase. Pyridoxal 5'-phosphate (PLP), a vitamin B_6 coenzyme, is required by serine hydroxymethyltransferase, which uses serine as a one-carbon donor for the generation of 5,10-methylenetetrahydrofolate (5,10-methylene THF) from THF. 5,10-methylene THF is then used in both methionine transmethylation cycle (not shown here) and thymidylate biosynthesis. *DHF, dihydrofolate; dUMP, deoxyuridine monophosphate; dTMP, deoxythymidine monophosphate (thymidylate); PLP, pyridoxal 5'-phosphate; THF, tetrahydrofolate.*

Deficiency

Severe deficiency of vitamin B_6 is uncommon. Alcoholics are thought to be most at risk of vitamin B_6 deficiency due to low dietary intakes and impaired metabolism of the vitamin. In the early 1950s, seizures were observed in infants as a result of severe vitamin B_6 deficiency caused by an error in the manufacture of infant formula (7). Abnormal electroencephalogram (EEG) patterns have also been reported in vitamin B_6-deficient adults. Other neurologic symptoms observed in severe vitamin B_6 deficiency include irritability, depression, and confusion; additional symptoms include inflammation of the tongue, sores or ulcers of the mouth, and ulcers of the skin at the corners of the mouth (12).

The Recommended Dietary Allowance (RDA)

Since vitamin B_6 is involved in many aspects of metabolism, especially in amino acid metabolic pathways, an individual's protein intake is likely to influence the requirement for vitamin B_6 (13). Unlike previous recommendations issued by the Food and Nutrition Board (FNB) of the Institute of Medicine, the most recent RDA for vitamin B_6 was not expressed in terms of protein intake, although the relationship was considered in setting the RDA (14). The current RDA was revised by the FNB in 1998 and is presented in **Table 1**.

Table 1. Recommended Dietary Allowance (RDA) for Vitamin B_6

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	0.1 (AI)	0.1 (AI)
Infants	7-12 months	0.3 (AI)	0.3 (AI)
Children	1-3 years	0.5	0.5
Children	4-8 years	0.6	0.6
Children	9-13 years	1.0	1.0
Adolescents	14-18 years	1.3	1.2
Adults	19-50 years	1.3	1.3
Adults	51 years and older	1.7	1.5
Pregnancy	all ages	-	1.9
Breast-feeding	all ages	-	2.0

Disease Prevention

Immune dysfunction

Several enzymatic reactions in the tryptophan-kynurenine pathway are dependent on vitamin B_6 coenzyme, pyridoxal 5'-phosphate (PLP) (see **Figure 2** above) (see Tryptophan metabolism). This pathway is known to be activated during pro-inflammatory immune responses and plays a critical role in immune tolerance of the fetus during pregnancy (15). Key intermediates in the tryptophan-kynurenine pathway are involved in the regulation of immune responses. Several tryptophan derivatives have been found to induce the death (apoptosis) or block the proliferation of certain types of immune cells, such as lymphocytes (in particular T-helper 1). They can also inhibit the production of pro-inflammatory cytokines (reviewed in 15). There is evidence to suggest that adequate vitamin B_6 intake is important for optimal immune system function, especially in older individuals (16, 17). Yet, chronic inflammation that triggers tryptophan degradation and underlies many diseases (e.g., cardiovascular disease and cancers) may precipitate the loss of PLP and increase vitamin B_6 requirements. Additional research is needed to evaluate whether vitamin B_6 intakes higher than the current RDA could prevent and/or reverse immune system impairments (see also Vitamin B_6 and inflammation).

Cardiovascular disease

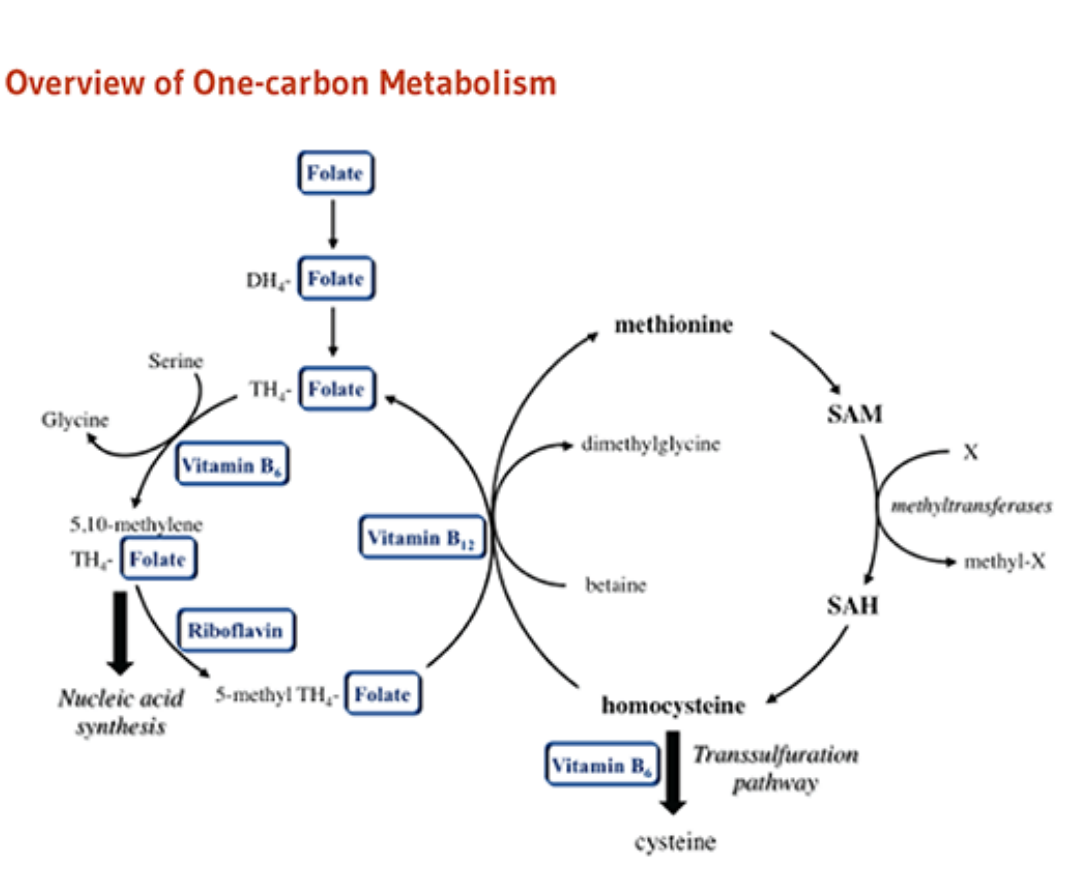
The use of multivitamin supplements (including vitamin B_6) has been associated with a 24% lower risk of incidental coronary artery disease (CAD) in a large prospective study of 80,082 women from the US Nurses' Health Study cohort (18). Using food frequency questionnaires, the authors observed that women in the highest quintile of vitamin B_6 intakes from both food and supplements (median, 4.6 mg/day) had a 34% lower risk of CAD compared to those in the lowest quintile (median, 1.1 mg/day). CAD is characterized by the abnormal stenosis (narrowing) of coronary arteries (generally due to atherosclerosis), which can result in a potentially fatal myocardial infarction (heart attack). More recently, a prospective study that followed a Japanese cohort of over 40,000 middle-aged individuals for 11.5 years reported a 48% lower risk of myocardial infarction in those in the highest (mean, 1.6 mg/day) versus lowest quintile (mean, 1.3 mg/day) of vitamin B_6 intakes in non-supplement users (19).

Early observational studies have also demonstrated an association between suboptimal pyridoxal 5'-phosphate (PLP) plasma level, elevated homocysteine blood level, and increased risk of cardiovascular disease (20-22). More recent research has confirmed that low plasma PLP status is a risk factor for CAD. In a case-control study, which included 184 participants with CAD and 516 healthy controls, low plasma PLP levels (<30 nanomoles/liter) were associated with a near doubling of CAD risk when compared to higher PLP levels (≥30 nanomoles/liter) (23). In a nested case-control study based on the Nurses' Health Study cohort and including 144 cases of myocardial infarction (of which 21 were fatal), women in the highest quartile of blood PLP levels (≥70 nanomoles/liter) had a 79% lower risk of myocardial infarction compared to those in the lowest quartile (<27.9 nanomoles/liter) (24).

Vitamin B_6 and homocysteine

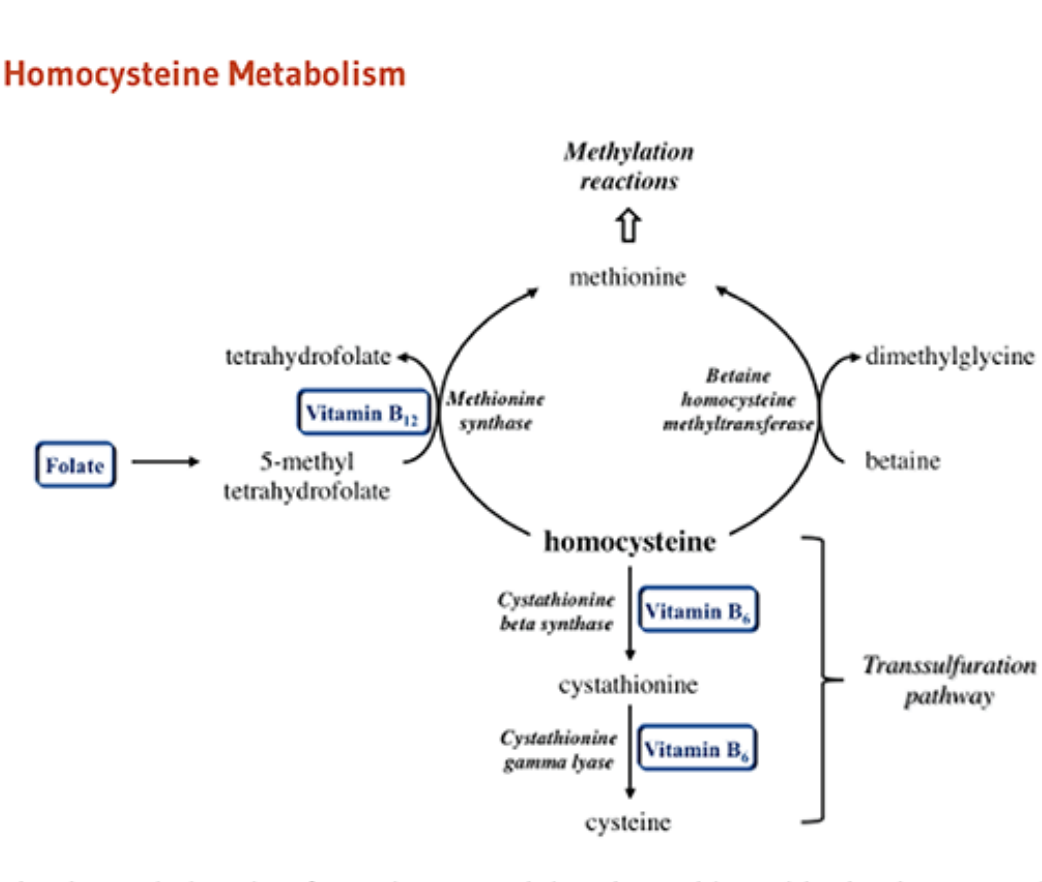
Even moderately elevated levels of homocysteine in the blood have been associated with increased risk for cardiovascular disease (CVD), including cardiac insufficiency (heart failure), CAD, myocardial infarction, and cerebrovascular attack (stroke) (25). During protein digestion, amino acids, including methionine, are released. Methionine is an essential amino acid and precursor of S-adenosylmethionine (SAM), the universal methyl donor for most methylation reactions, including the methylation of DNA, RNA, proteins, and phospholipids (**Figure 4**). Homocysteine is an intermediate in the metabolism of methionine. Healthy individuals utilize two different pathways to regenerate methionine from homocysteine in the methionine remethylation cycle (**Figure 5**). One pathway relies on the vitamin B_{12}-dependent methionine synthase and the methyl donor, 5-methyl tetrahydrofolate (a folate derivative), to convert homocysteine back to methionine. The other reaction is catalyzed by betaine homocysteine methyltransferase, which uses betaine as a source of methyl groups for the formation of methionine from homocysteine. Moreover, two PLP-dependent enzymes are required to convert homocysteine to the amino acid cysteine in homocysteine transsulfuration pathway: cystathionine β synthase and cystathionine γ lyase (**Figure 5**). Thus, the amount of homocysteine in the blood may be influenced by nutritional status of at least three B vitamins, namely folate, vitamin B_{12}, and vitamin B_6.

Figure 4. Overview of One-carbon Metabolism



SAM, S-adenosylmethionine; SAH, S-adenosylhomocysteine; TH4-folate, tetrahydrofolate.

Figure 5. Homocysteine Metabolism



Homocysteine is methylated to form the essential amino acid methionine in two pathways. The reaction of homocysteine remethylation catalyzed by the vitamin B_{12}-dependent methionine synthase captures a methyl group from the folate-dependent one-carbon pool (5-methyl tetrahydrofolate). A second pathway requires betaine (N,N,N-trimethylglycine) as a methyl donor for the methylation of homocysteine catalyzed by betaine homocysteine methyltransferase. The catabolic pathway of homocysteine, known as transsulfuration pathway, converts homocysteine to the amino acid cysteine via two vitamin B_6 (PLP)-dependent enzymes: cystathionine β synthase catalyzes the condensation of homocysteine with serine to form cystathionine, and cystathionine is then converted to cysteine, α-ketobutyrate, and ammonia by cystathionine γ lyase.

Deficiencies in one or all of these B vitamins may affect both remethylation and transsulfuration processes and result in abnormally elevated homocysteine levels. An early study found that vitamin B_6 supplementation could lower blood homocysteine levels after an oral dose of methionine was given (i.e., a methionine load test) (26), but vitamin B_6 supplementation might not be effective in decreasing fasting levels of homocysteine. In a recent study conducted in nine healthy young volunteers, the rise of homocysteine during the postprandial period (after a meal) was found to be greater with marginal vitamin B_6 deficiency (mean plasma PLP level of 19 nanomoles/liter) as compared to vitamin B_6 sufficiency (mean PLP level of 49 nanomoles/liter) (27). The authors reported an increased rate of cystathionine synthesis with vitamin B_6 restriction, suggesting that homocysteine catabolism in the transsulfuration may be maintained or enhanced in response to a marginal reduction in PLP availability. Yet, the flux ratio between methionine cycle and transsulfuration pathway appeared to favor homocysteine clearance by remethylation rather than transsulfuration in six out of nine participants (27).

Numerous randomized controlled trials, many in subjects with existing hyperhomocysteinemia and vascular dysfunction, have demonstrated that supplementation with folic acid, alone or combined with vitamin B_6 and vitamin B_{12}, could effectively reduce fasting plasma homocysteine concentrations. In 19 intervention studies recently included in a meta-analysis, reductions in homocysteine level in the blood following B-vitamin supplementation ranged between 7.6% and 51.7% compared to baseline levels (28). In contrast, studies supplementing individuals with only vitamin B_6 have usually failed to show an effect on fasting levels of homocysteine (29, 30). Of the three supplemental B vitamins, folic acid appears to be the main determinant in the regulation of fasting homocysteine levels when there is no coexisting deficiency of vitamin B_{12} or vitamin B_6 (31). Yet, the effect of homocysteine lowering on CVD risk reduction is debated. A recent meta-analysis of nine randomized controlled trials reported a 10% reduction in stroke events with supplemental B vitamins, with greater benefits for high-risk subjects (e.g., those with kidney disease) (32). However, most systematic reviews and meta-analyses of B-vitamin intervention studies to date have indicated a lack of causality between the decrease of fasting homocysteine levels and the prevention of cardiovascular events (28, 33-35). Moreover, B-vitamin supplementation trials in high-risk subjects have not resulted in significant changes in carotid intima-media thickness (CIMT) and flow-mediated dilation (FMD) of the brachial artery, two markers of vascular health used to assess atherosclerotic progression (36). Finally, in the Western Norway B Vitamin Intervention Trial (WENBIT), a randomized, double-blind, placebo-controlled trial in 87 subjects with suspected CAD, vitamin B_6 supplementation (40 mg/day of pyridoxine) for a median of 10 months had no effect on coronary stenosis progression, assessed by quantitative angiography (37).

It has been suggested that antiplatelet therapy used in the primary prevention of CVD might interfere with the effect of homocysteine lowering by B vitamins on CVD risk (38). In this context, a post-hoc subgroup analysis of the multicenter, randomized, double blind, placebo-controlled VITATOPS trial (39) proposed that the small benefit of homocysteine-lowering by B vitamins might be cancelled in patients treated with antiplatelet drugs (40). Yet, the benefit of B-vitamin supplementation in primary prevention (i.e., in non-antiplatelet users) remains to be established.

Vitamin B_6 and inflammation

A growing body of evidence currently suggests that low vitamin B_6 status may increase the risk of cardiovascular disease through mechanisms independent of homocysteine lowering (41-43). Markers of immune activation and inflammation have been associated with hyperhomocysteinemia (homocysteine levels >15 micromoles/liter) in individuals with coronary artery disease (CAD) (44). In fact, inflammation is involved in the early steps of atherosclerosis in which lipids deposit in plaques (known as atheromas) within arterial walls and increase the risk of CAD (45). In a case-control study that included 267 patients with CAD and 475 healthy controls, plasma PLP concentrations were inversely correlated with the levels of two markers of systemic inflammation, C-reactive protein (CRP) and fibrinogen (46). Yet, the study suggested that suboptimal PLP levels (<36.3 nanomoles/liter) might contribute to an increased risk of CAD independently of inflammation since the risk was unchanged after adjustment for inflammation markers (unadjusted odds ratio (OR): 1.71 vs. multivariate adjusted OR: 1.73). Furthermore, the analysis of inflammation markers in 2,686 participants of the US National Health and Nutrition Examination Survey (NHANES) 2003-2004 indicated that serum CRP concentrations were inversely related to total vitamin B_6 intakes (from both food and supplements). Specifically, the risk of having serum CRP levels greater than 10 mg/L (corresponding to high inflammatory activity) was 57% higher in individuals with vitamin B_6 intakes lower than 2 mg/day compared to those with intakes equal to and above 5 mg/day (41). In addition, the prevalence of inadequate vitamin B_6 status (plasma PLP levels <20 nanomoles/liter) with intakes lower than 5 mg/day was systematically greater in individuals with high versus low serum CRP concentrations (>10 mg/L vs. ≤3 mg/L), suggesting that inflammation might impair vitamin B_6 metabolism. These observations were confirmed in the study of another cohort (Framingham Offspring Study) in which vitamin B_6 status was linked to an overall inflammatory score based on the levels of 13 inflammation markers (including CRP, fibrinogen, tumor necrosis factor-α, and interleukin-6) (42). Specifically, plasma PLP levels were 24% lower in individuals in the highest versus lowest tertile of inflammatory score. Moreover, the inverse correlation between PLP levels and inflammatory scores remained significant regardless of vitamin B_6 intakes, questioning again the nature of this relationship. Interestingly, a recent analysis of data collected in the WENBIT study demonstrated that systemic inflammation was associated with an increased degradation of pyridoxal (PL) to 4-pyridoxic acid (PA), supporting the use of the ratio PA:(PL+PLP) as a marker of both vitamin B_6 status and systemic inflammation (47). Finally, while inflammation may contribute to lower vitamin B_6 status, current evidence fails to support a role for vitamin B_6 in the control of inflammation in patients with cardiovascular disease (48, 49).

Cognitive decline and Alzheimer's disease

A few observational studies have linked cognitive decline and Alzheimer's disease (AD) in the elderly with inadequate status of folate, vitamin B_{12}, and vitamin B_6 (50). Yet, the relationship between B vitamins and cognitive health in aging is complicated by both the high prevalence of hyperhomocysteinemia and signs of systemic inflammation in elderly people (51). On the one hand, since inflammation may impair vitamin B_6 metabolism, low serum PLP levels may well be caused by processes related to aging rather than by malnutrition. On the other hand, high serum homocysteine may possibly be a risk factor for cognitive decline in the elderly, although the matter remains under debate. Specifically, the meta-analysis of 19 randomized, placebo-controlled trials of B-vitamin supplementation failed to report any difference in several measures of cognitive function between treatment and placebo groups, despite the treatment effectively lowering homocysteine levels (52). In a recent randomized, double-blind, placebo-controlled study of 2,695 stroke survivors with or without cognitive impairments, daily supplementation with 2 mg of folic acid, 0.5 mg of vitamin B_{12}, and 25 mg of vitamin B_6 for 3.4 years resulted in significant reductions in mean homocysteine levels (by 28% and 43% in cognitively unimpaired and impaired patients, respectively) compared to placebo. Yet, the B-vitamin intervention had no effect on either the incidence of newly diagnosed cognitive impairments or on measures of cognitive performance when compared to placebo (53). In contrast, another recent placebo-controlled trial found that a daily B-vitamin regimen that led to significant homocysteine lowering in high-risk elderly individuals could limit the progressive atrophy of gray matter brain regions associated with the AD process (54). Yet, the authors attributed the changes in homocysteine levels primarily to vitamin B_{12}. Because of mixed findings, it is presently unclear whether supplementation with B vitamins might blunt cognitive decline in the elderly. Evidence is needed to determine whether marginal B-vitamin deficiencies, which are relatively common in the elderly, even contribute to age-associated declines in cognitive function, or whether both result from processes associated with aging and/or disease.

Depression

Late-life depression is a common disorder sometimes occurring after acute illnesses, such as hip fracture or stroke (55, 56). Coexistence of symptoms of depression and low vitamin B_6 status (plasma PLP level ≤20 nanomoles/liter) has been reported in a few cross-sectional studies (57, 58). In a prospective study of 3,503 free-living people aged 65 and older from the Chicago Health and Aging Project, total vitamin B_6 intakes (but not dietary intakes alone) were inversely correlated with the incidence of depressive symptoms during a mean follow-up period of 7.2 years (59). In a randomized, double-blind, placebo-controlled trial in 563 individuals who suffered from a recent stroke, daily supplementation of 2 mg of folic acid, 0.5 mg of vitamin B_{12}, and 25 mg of vitamin B_6 halved the risk of developing a major depressive episode during a mean follow-up period of 7.1 years (60). This reduction in risk was associated with a 25% lower level of plasma homocysteine in supplemented patients compared to controls. Additional evidence is needed to evaluate whether B vitamins could be included in the routine management of older people at high risk for depression.

Cancer

Chronic inflammation that underlies most cancers may enhance vitamin B_6 degradation (see Vitamin B_6 and inflammation). In addition, because PLP is required for the methionine cycle, homocysteine catabolism, and thymidylate synthesis, low vitamin B_6 status might affect these pathways and potentially increase the risk for chronic conditions. The systematic review of nine prospective studies found either inverse or positive associations between vitamin B_6 intakes and colorectal cancer (CRC) risk (61). Inconsistent evidence regarding the link between vitamin B_6 intakes and breast cancer was also recently reported in a meta-analysis (62). Yet, a prospective study that followed nearly 500,000 older adults for nine years observed that the risk of esophageal and stomach cancers was lower in participants in the highest versus lowest quintile of total vitamin B_6 intakes (median values, 2.7 mg/day vs. 1.4 mg/day) (63). Additionally, a meta-analysis of four nested case-control studies reported a 48% reduction in CRC risk in the highest versus lowest quartile of blood PLP level (61). Another meta-analysis of five nested case-control studies found higher versus lower serum PLP levels to be associated with a 29% lower risk of breast cancer in postmenopausal, but not premenopausal, women (62).

Very few randomized, placebo-controlled trials investigating the nature of the association between B vitamins and cancer risk have focused on vitamin B_6. Two earlier studies conducted in subjects with coronary artery disease failed to observe any benefit of supplemental vitamin B_6 (40 mg/day) on CRC risk and mortality (reviewed in 64). A recent randomized, double-blind, placebo-controlled study conducted in 1,470 women with high cardiovascular risk showed that daily supplementation with 2.5 mg of folic acid, 1 mg of vitamin B_{12}, and 50 mg of vitamin B_6 for a mean treatment period of 7.3 years had no effect on the risk of developing colorectal adenoma when compared to placebo (65).

Kidney stones

A large prospective study examined the relationship between vitamin B_6 intake and the occurrence of symptomatic kidney stones in women. A group of more than 85,000 women without a prior history of kidney stones were followed over 14 years, and those who consumed 40 mg or more of vitamin B_6 daily had only two-thirds the risk of developing kidney stones compared with those who consumed 3 mg or less (66). However, in a group of more than 45,000 men followed for 14 years, no association was found between vitamin B_6 intake and the occurrence of kidney stones (67). Limited experimental data have suggested that supplementation with high doses of pyridoxamine may help decrease the formation of calcium oxalate kidney stones and reduce urinary oxalate levels, an important determinant of calcium oxalate kidney stone formation (68, 69). Presently, the relationship between vitamin B_6 intake and the risk of developing kidney stones requires further study before any recommendations can be made.

Disease Treatment

Vitamin B_6 supplements at pharmacologic doses (i.e., doses much larger than those needed to prevent deficiency) have been used in an attempt to treat a wide variety of conditions, some of which are discussed below.

Metabolic diseases

A few rare inborn metabolic disorders, including pyridoxine-dependent epilepsy (PDE) and pyridoxamine 5'-phosphate oxidase (PNPO) deficiency, are the cause of early-onset epileptic encephalopathies that are found to be responsive to pharmacologic doses of vitamin B_6. In individuals affected by PDE and PNPO deficiency, PLP bioavailability is limited, and treatment with pyridoxine and/or PLP have been used to alleviate or abolish epileptic seizures characterizing these conditions (70, 71). Pyridoxine therapy, along with dietary protein restriction, is also used in the management of vitamin B_6 responsive homocystinuria caused by the deficiency of the PLP-dependent enzyme, cystathionine β synthase (72).

Morning sickness

Nausea and vomiting in pregnancy (NVP), often referred to as morning sickness, can affect up to 85% of women during early pregnancy and usually lasts between 12 and 16 weeks (73). Vitamin B_6 has been used since the 1940s to treat nausea during pregnancy. Vitamin B_6 was originally included in the medication Bendectin, which was prescribed for NVP treatment and later withdrawn from the market due to unproven concerns that it increased the risk for birth defects. Vitamin B_6 itself is considered safe during pregnancy and has been used in pregnant women without any evidence of fetal harm (74). The results of two double-blind, placebo-controlled trials, including 401 pregnant women that used 25 mg of pyridoxine every eight hours for three days (75) or 10 mg of pyridoxine every eight hours for five days (76), suggested that vitamin B_6 may be beneficial in reducing nausea. A recent systematic review of randomized controlled trials on NVP symptoms during early pregnancy found supplemental vitamin B_6 to be somewhat effective (77). It should be noted that NVP usually resolves without any treatment, making it difficult to perform well-controlled trials. More recently, NVP symptoms were evaluated using Pregnancy Unique Quantification of Emesis (PUQE) scores in a randomized, double-blind, placebo-controlled study conducted in 256 pregnant women (7-14 weeks' gestation) suffering from NVP (78). Supplementation with pyridoxine and the drug doxylamine significantly improved NVP symptoms, as assessed by lower PUQE scores compared to placebo. Moreover, more women supplemented with pyridoxine-doxylamine (48.9%) than placebo-treated (32.8%) asked to continue their treatment at the end of the 15-day trial. The American and Canadian Colleges of Obstetrics and Gynecology have recommended the use of vitamin B_6 (pyridoxine hydrochloride, 10 mg) and doxylamine succinate (10 mg) as first-line therapy for NVP (73).

Premenstrual syndrome

Premenstrual syndrome (PMS) refers to a cluster of symptoms, including but not limited to fatigue, irritability, moodiness/depression, fluid retention, and breast tenderness, that begin sometime after ovulation (mid-cycle) and subside with the onset of menstruation (the monthly period). A systematic review and meta-analysis of nine randomized, placebo-controlled trials suggested that supplemental vitamin B_6, up to 100 mg/day, may be of value to treat PMS, including mood symptoms; however, only limited conclusions could be drawn because most of the studies were of poor quality (79). Another more recent review of 13 randomized controlled studies also emphasized the need for conclusive evidence before recommendations can be made (80).

Depression

The importance of PLP-dependent enzymes in the synthesis of several neurotransmitters (see Nervous system function) has led researchers to consider whether vitamin B_6 deficiency may contribute to the onset of depressive symptoms (see Disease Prevention). There is limited evidence suggesting that supplemental vitamin B_6 may have therapeutic efficacy in the management of depression. In a randomized, placebo-controlled trial conducted in 225 elderly patients hospitalized for acute illness, a six-month intervention with daily multivitamin/mineral supplements improved nutritional B-vitamin status and decreased the number and severity of depressive symptoms when compared to placebo (81). In addition, while supplement intake effectively reduced plasma homocysteine levels compared to placebo, the effect of supplementation on depressive symptoms at the end of the trial was greater in treated subjects in the lowest versus highest quartile of homocysteine levels (≤10 micromoles/liter vs. ≥16.1 micromoles/liter) (82). Yet, the etiology of late-onset depression is unclear and evidence is currently lacking to suggest whether supplemental B vitamins (including vitamin B_6) could relieve depressive symptoms.

Carpal tunnel syndrome

Carpal tunnel syndrome (CTS) causes numbness, pain, and weakness of the hand and fingers due to compression of the median nerve at the wrist. It may result from repetitive stress injury of the wrist or from soft-tissue swelling, which sometimes occurs with pregnancy or hypothyroidism. Early studies by the same investigator suggested that supplementation with 100-200 mg/day of vitamin B_6 for several months might improve CTS symptoms in individuals with low vitamin B_6 status (83, 84). In addition, a cross-sectional study in 137 men not taking vitamin supplements found that decreased blood levels of PLP were associated with increased pain, tingling, and nocturnal awakening—all symptoms of CTS (85). However, studies using electrophysiological measurements of median nerve conduction have largely failed to find an association between vitamin B_6 deficiency and CTS (86). While a few studies have noted some symptomatic relief with vitamin B_6 supplementation, double-blind, placebo-controlled trials have not generally found vitamin B_6 to be effective in treating CTS (86). Yet, despite its equivocal effectiveness, vitamin B_6 supplementation is sometimes used in complementary therapy in an attempt to avoid hand surgery. Patients taking high doses of vitamin B_6 should be advised by a physician and monitored for vitamin B_6-related toxicity symptoms (see Toxicity) (87).

Sources

Food sources

The analysis of data collected in the US NHANES 2003-2004 has indicated that vitamin B_6 intakes from food only averaged about 1.9 mg/day (88). Yet, despite values well above the current RDA, total vitamin B_6 intakes (combining food and supplements) below 2 mg/day appear to be associated with relatively high proportions of low vitamin B_6 status in all age groups (see Supplements). Many plant foods contain a unique form of vitamin B_6 called pyridoxine glucoside; this form of vitamin B_6 appears to be only about half as bioavailable as vitamin B_6 from other food sources or supplements (7). Vitamin B_6 in a mixed diet has been found to be approximately 75% bioavailable (14). In most cases, including foods in the diet that are rich in vitamin B_6 should supply enough to meet the current RDA. However, those who follow a very restricted vegetarian diet might need to increase their vitamin B_6 intake by eating foods fortified with vitamin B_6 or by taking a supplement. Some foods that are relatively rich in vitamin B_6 and their vitamin B_6 content in milligrams (mg) are listed in **Table 2**. For more information on the nutrient content of specific foods, search USDA's FoodData Central.

Table 2. Some Food Sources of Vitamin B_6

Food	Serving	Vitamin B_6 (mg)
Fortified breakfast cereal	1 cup	0.5-2.5
Salmon, wild (cooked)	3 ounces*	0.48-0.80
Potato, Russet, with skin (baked)	1 medium	0.70
Turkey, light meat (cooked)	3 ounces	0.69
Avocado	1 medium	0.52
Chicken, light meat without skin (cooked)	3 ounces	0.51
Spinach (cooked)	1 cup	0.44
Banana	1 medium	0.43
Dried plums, pitted	1 cup	0.36
Hazelnuts (dry roasted)	1 ounce	0.18
Vegetable juice cocktail	6 ounces	0.13
*A three-ounce serving of meat or fish is about the size of a deck of cards.		

Supplements

Vitamin B_6 is available as pyridoxine hydrochloride in multivitamin, vitamin B-complex, and vitamin B_6 supplements (89). In NHANES 2003-2004, low vitamin B_6 status (plasma PLP level <20 nanomoles/liter) was reported in 24% of non users of supplements and 11% of supplement users. Moreover, total vitamin B_6 intakes (from food and supplements) lower than 2 mg/day were associated with high proportions of low plasma PLP levels: 16% in men aged 13-54 years, 24% in menstruating women, and 26% in individuals aged 65 years and older. Finally, the prevalence of low PLP levels was found to be greater in individuals consuming less than 2 mg/day of vitamin B_6 compared to higher intakes. For example, only 14% of men and women aged 65 and older had low PLP values with total vitamin B_6 intakes of 2-2.9 mg/day compared to 26% in those consuming less than 2 mg/day of vitamin B_6 (88).

Safety

Toxicity

Because adverse effects have only been documented from vitamin B_6 supplements and never from food sources, safety concerning only the supplemental form of vitamin B_6 (pyridoxine) is discussed. Although vitamin B_6 is a water-soluble vitamin and is excreted in the urine, long-term supplementation with very high doses of pyridoxine may result in painful neurological symptoms known as sensory neuropathy. Symptoms include pain and numbness of the extremities and in severe cases, difficulty walking. Sensory neuropathy typically develops at doses of pyridoxine in excess of 1,000 mg per day. However, there have been a few case reports of individuals who developed sensory neuropathies at doses of less than 500 mg daily over a period of months. Yet, none of the studies in which an objective neurological examination was performed reported evidence of sensory nerve damage at intakes below 200 mg pyridoxine daily (90). To prevent sensory neuropathy in virtually all individuals, the Food and Nutrition Board of the Institute of Medicine set the tolerable upper intake level (UL) for pyridoxine at 100 mg/day for adults (**Table 3**) (14). Because placebo-controlled studies have generally failed to show therapeutic benefits of high doses of pyridoxine, there is little reason to exceed the UL of 100 mg/day.

Table 3. Tolerable Upper Intake Level (UL) for Vitamin B_6

Age Group	UL (mg/day)
Infants 0-12 months	Not possible to establish*
Children 1-3 years	30
Children 4-8 years	40
Children 9-13 years	60
Adolescents 14-18 years	80
Adults 19 years and older	100
*Source of intake should be from food and formula only.	

Drug interactions

Certain medications interfere with the metabolism of vitamin B_6; therefore, some individuals may be vulnerable to a vitamin B_6 deficiency if supplemental vitamin B_6 is not taken. In the NHANES 2003-2004 analysis, significantly more current and past users of oral contraceptives (OCs) among menstruating women had low plasma PLP levels compared to women who have never used OCs, suggesting that the estrogen content of OCs may interfere with vitamin B_6 metabolism (see Side effects of oral contraceptives) (88). Anti-tuberculosis medications (e.g., isoniazid and cycloserine), the metal chelator penicillamine, and anti-parkinsonian drugs like L-Dopa can all form complexes with vitamin B_6 and limit its bioavailability, thus creating a functional deficiency. PLP bioavailability may also be reduced by methylxanthines, such as theophylline used to treat certain respiratory conditions (7). The long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs; e.g. celecoxib and naproxen) may also impair vitamin B_6 metabolism (91). Conversely, high doses of vitamin B_6 have been found to decrease the efficacy of two anticonvulsants, phenobarbital and phenytoin, and of L-Dopa (6, 90).

Side effects of oral contraceptives

Because vitamin B_6 is required for the metabolism of the amino acid tryptophan, the tryptophan load test (an assay of tryptophan metabolites after an oral dose of tryptophan) has been used as a functional assessment of vitamin B_6 status. Abnormal tryptophan load tests in women taking high-dose oral contraceptives (OCs) in the 1960s and 1970s suggested that these women were vitamin B_6 deficient, which led to the prescription of high doses of vitamin B_6 (100-150 mg/day) to women taking OCs. However, most other indices of vitamin B_6 status were normal in women on high-dose OCs, and the estrogen content of OCs appeared to be more likely responsible for the abnormality in tryptophan metabolism (88). Yet, more recently, the use of lower dose formulations has also been associated with vitamin B_6 inadequacy (88, 92). Although it is not known whether OCs actually impair vitamin B_6 metabolism or merely affect the tissue distribution of PLP, the use of OCs may place women at higher risk of vitamin B_6 deficiency when they discontinue OCs and become pregnant (93). Whether OC users are at higher risk of cardiovascular disease despite normal homocysteine levels also needs to be determined. Finally, although high doses of vitamin B_6 (pyridoxine) have demonstrated no benefit in preventing the risk of side effects from OCs (94), the use of vitamin B_6 supplements may be warranted in current and past OC users.

Linus Pauling Institute Recommendation

The Linus Pauling Institute supports the RDA for vitamin B_6. LPI recommends that all adults take a daily multivitamin/mineral supplement, which usually contains at least 2 mg of vitamin B_6. This amount is slightly above the RDA but still 50 times lower than the tolerable upper intake level (UL) set by the Food and Nutrition Board (see Safety).

Older adults (>50 years)

Early metabolic studies have indicated that the requirement for vitamin B_6 in older adults is approximately 2 mg daily (95). Yet, the analysis of the US population survey (NHANES) 2003-2004 showed that adequate vitamin B_6 status and low homocysteine levels were associated with total vitamin B_6 intakes equal to and above 3 mg/day in people aged 65 years and older (88). The Linus Pauling Institute recommends that older adults take a multivitamin/mineral supplement, which provides at least 2.0 mg of vitamin B_6 daily.

Summary

- Vitamin B_{12} or cobalamin plays essential roles in folate metabolism and in the synthesis of the citric acid cycle intermediate, succinyl-CoA. *(More information)*
- Vitamin B_{12} deficiency is commonly associated with chronic stomach inflammation, which may contribute to an autoimmune vitamin B_{12} malabsorption syndrome called pernicious anemia and to a food-bound vitamin B_{12} malabsorption syndrome. Impairment of vitamin B_{12} absorption can cause megaloblastic anemia and neurologic disorders in deficient subjects. *(More information)*
- Normal function of the digestive system required for food-bound vitamin B_{12} absorption is commonly impaired in individuals over 60 years of age, placing them at risk for vitamin B_{12} deficiency. *(More information)*
- Vitamin B_{12} and folate are important for homocysteine metabolism. Elevated homocysteine levels in blood are a risk factor for cardiovascular disease (CVD). Although B vitamin supplementation has been proven effective to control homocysteine levels, current data from intervention trials have not shown that lowering homocysteine levels decreases CVD risk. *(More information)*
- The preservation of DNA integrity is dependent on folate and vitamin B_{12} availability. Poor vitamin B_{12} status has been linked to increased risk of breast cancer in some, but not all, observational studies. There is a need to evaluate whether supplemental vitamin B_{12}, along with folic acid, could help reduce breast cancer incidence. *(More information)*
- Low maternal vitamin B_{12} status has been associated with an increased risk of neural tube defects (NTD), but it is not known whether vitamin B_{12} supplementation could help reduce the risk of NTD. *(More information)*
- Vitamin B_{12} is essential for the preservation of the myelin sheath around neurons and for the synthesis of neurotransmitters. While hyperhomocysteinemia may increase the risk of cognitive impairment, it is not clear whether vitamin B_{12} deficiency contributes to the risk of dementia in the elderly. Although B-vitamin supplementation lowers homocysteine levels in older subjects, the long-term benefit is not yet known. *(More information)*
- Both depression and osteoporosis have been linked to diminished vitamin B_{12} status and high homocysteine levels. *(More information)*
- Products of animal origin constitute the primary source of vitamin B_{12}. Older individuals and vegans are advised to use vitamin B_{12} fortified foods and supplements to meet their needs. *(More information)*
- The long-term use of certain medications, such as inhibitors of stomach acid secretion, can adversely affect vitamin B_{12} absorption. *(More information)*

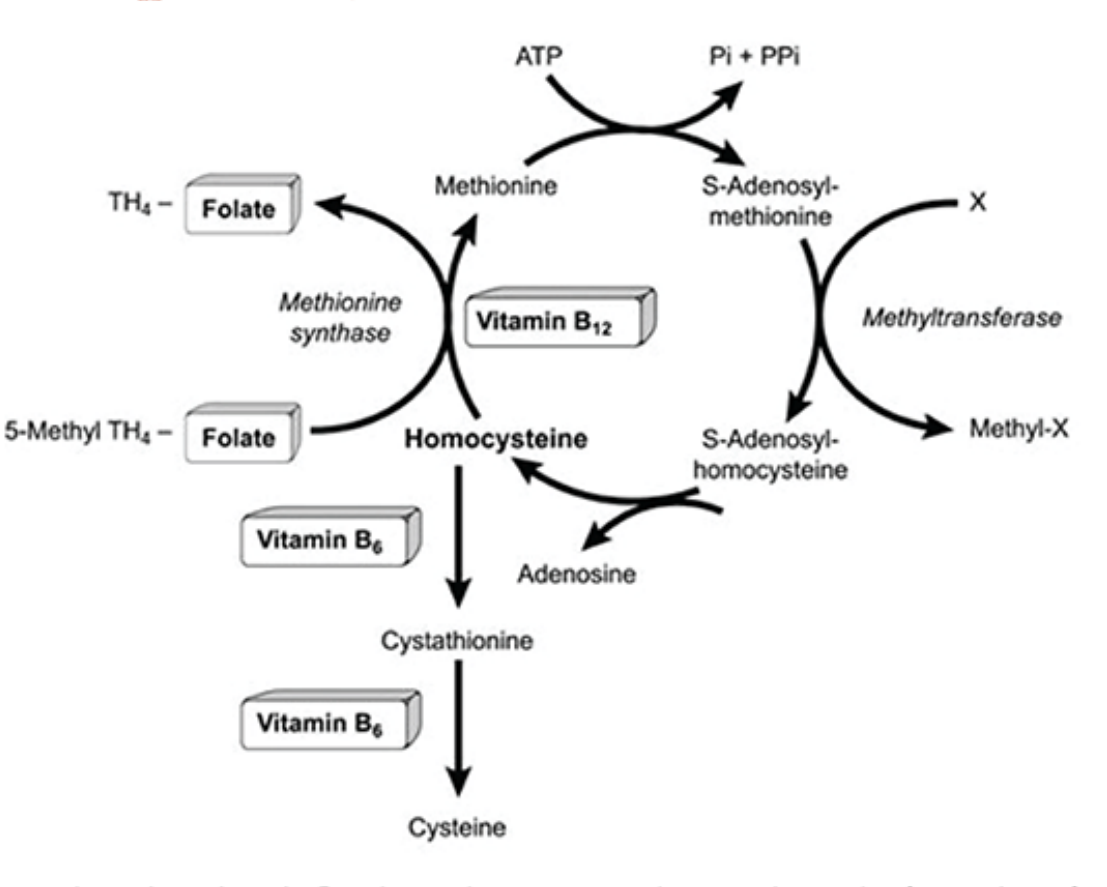
Vitamin B_{12} has the largest and most complex chemical structure of all the vitamins. It is unique among vitamins in that it contains a metal ion, cobalt. For this reason cobalamin is the term used to refer to compounds having vitamin B_{12} activity. Methylcobalamin and 5-deoxyadenosylcobalamin are the forms of vitamin B_{12} used in the human body (1). The form of cobalamin used in most nutritional supplements and fortified foods, cyanocobalamin, is readily converted to 5-deoxyadenosylcobalamin and methylcobalamin in the body. In mammals, cobalamin is a cofactor for only two enzymes, methionine synthase and L-methylmalonyl-coenzyme A mutase (2).

Function

Cofactor for methionine synthase

Methylcobalamin is required for the function of the folate-dependent enzyme, methionine synthase. This enzyme is required for the synthesis of the amino acid, methionine, from homocysteine. Methionine in turn is required for the synthesis of S-adenosylmethionine, a methyl group donor used in many biological methylation reactions, including the methylation of a number of sites within DNA, RNA, and proteins (3). Aberrant methylation of DNA and proteins, which causes alterations in chromatin structure and gene expression, are a common feature of cancer cells. Inadequate function of methionine synthase can lead to an accumulation of homocysteine, which has been associated with increased risk of cardiovascular disease (**Figure 1**).

Figure 1. Vitamin B_{12} and Homocysteine Metabolism

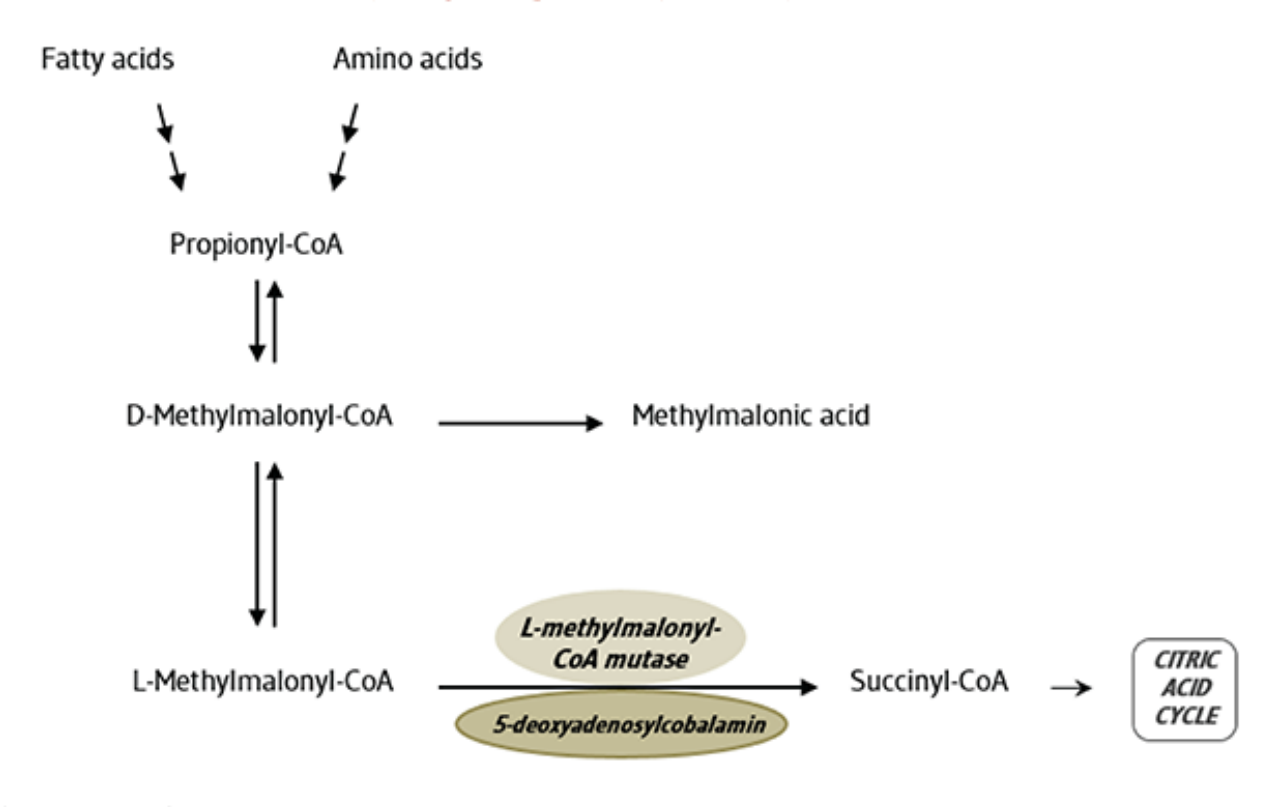


Methionine synthase is a vitamin B_{12}-dependent enzyme that catalyzes the formation of methionine from homocysteine using 5-methyltetrahydrofolate (5-methyl TH_4), a folate derivative, as a methyl donor. Another pathway catalyzed by betaine homocysteine methyltransferase also remethylates homocysteine to methionine using betaine as a methyl donor (not shown here). Methionine, in the form of S-adenosylmethionine, is required for most biological methylation reactions, including DNA methylation.

Cofactor for L-methylmalonyl-coenzyme A mutase

5-Deoxyadenosylcobalamin is required by the enzyme that catalyzes the conversion of L-methylmalonyl-coenzyme A to succinyl-coenzyme A (succinyl-CoA), which then enters the citric acid cycle (**Figure 2**). Succinyl-CoA plays an important role in the production of energy from lipids and proteins and is also required for the synthesis of hemoglobin, the oxygen-carrying pigment in red blood cells (3).

Figure 2. Metabolic Pathway Requiring 5-deoxyadenosylcobalamin



CoA, coenzyme A.

Deficiency

In healthy adults, vitamin B_{12} deficiency is uncommon, mainly because total body stores can exceed 2,500 μg, daily turnover is slow, and dietary intake of only 2.4 μg/day is sufficient to maintain adequate vitamin B_{12} status (see RDA) (4). In elderly individuals, vitamin B_{12} deficiency is more common mainly because of impaired intestinal absorption that can result in marginal to severe vitamin B_{12} deficiency in this population.

Causes of vitamin B_{12} deficiency

Intestinal malabsorption, rather than inadequate dietary intake, can explain most cases of vitamin B_{12} deficiency (5). Absorption of vitamin B_{12} from food requires normal function of the stomach, pancreas, and small intestine. Stomach acid and enzymes free vitamin B_{12} from food, allowing it to bind to R-protein (also known as transcobalamin-1 or haptocorrin), found in saliva and gastric fluids. In the alkaline environment of the small intestine, R-proteins are degraded by pancreatic enzymes, freeing vitamin B_{12} to bind to intrinsic factor (IF), a protein secreted by specialized cells in the stomach. Receptors on the surface of the ileum (final part of the small intestine) take up the IF-B_{12} complex only in the presence of calcium, which is supplied by the pancreas (5). Vitamin B_{12} can also be absorbed by passive diffusion, but this process is very inefficient—only about 1% absorption of the vitamin B_{12} dose is absorbed passively (2). The prevalent causes of vitamin B_{12} deficiency are (1) an autoimmune condition known as pernicious anemia, and (2) a disorder called food-bound vitamin B_{12} malabsorption. Both conditions have been associated with a chronic inflammatory disease of the stomach known as atrophic gastritis.

Atrophic gastritis

Atrophic gastritis is thought to affect 10%-30% of people over 60 years of age (6). The condition is frequently associated with the presence of autoantibodies directed toward stomach cells (see Pernicious anemia) and/or infection by the bacteria, *Helicobacter pylori* (*H. pylori*) (7). *H. pylori* infection induces chronic inflammation of the stomach, which may progress to peptic ulcer disease, atrophic gastritis, and/or gastric cancer in some individuals. Diminished gastric function in individuals with atrophic gastritis can result in bacterial overgrowth in the small intestine and cause food-bound vitamin B_{12} malabsorption. Vitamin B_{12} levels in serum, plasma, and gastric fluids are significantly decreased in individuals with *H. pylori* infection, and eradication of the bacteria has been shown to significantly improve vitamin B_{12} serum concentrations (8).

Pernicious anemia

Pernicious anemia has been estimated to be present in approximately 2% of individuals over 60 years of age (9). Although anemia is often a symptom, the condition is actually the end stage of an autoimmune inflammation of the stomach known as autoimmune atrophic gastritis, resulting in destruction of stomach cells by one's own antibodies (autoantibodies). Progressive destruction of the cells that line the stomach causes decreased secretion of acid and enzymes required to release food-bound vitamin B_{12}. Antibodies to intrinsic factor (IF) bind to IF preventing formation of the IF-B_{12} complex, further inhibiting vitamin B_{12} absorption. About 20% of the relatives of pernicious anemia patients also have the condition, suggesting a genetic predisposition. It is also thought that *H. pylori* infection could be involved in initiating the autoimmune response in a subset of individuals (10). Further, co-occurrence of autoimmune atrophic gastritis with other autoimmune conditions, especially autoimmune thyroiditis and type 1 diabetes mellitus, has been reported (11, 12).

Treatment of pernicious anemia generally requires injections of vitamin B_{12} to bypass intestinal absorption. High-dose oral supplementation is another treatment option, because consuming 1,000 μg (1 mg)/day of vitamin B_{12} orally should result in the absorption of about 10 μg/day (1% of dose) by passive diffusion. In fact, high-dose oral therapy is considered to be as effective as intramuscular injection (4).

Food-bound vitamin B_{12} malabsorption

Food-bound vitamin B_{12} malabsorption is defined as an impaired ability to absorb food- or protein-bound vitamin B_{12}; individuals with this condition can fully absorb the free form (13). While the condition is the major cause of poor vitamin B_{12} status in the elderly population, it is usually associated with atrophic gastritis, a chronic inflammation of the lining of the stomach that ultimately results in the loss of glands in the stomach (atrophy) and decreased stomach acid production (see Atrophic gastritis). Because stomach acid is required for the release of vitamin B_{12} from the proteins in food, vitamin B_{12} absorption is diminished. Decreased stomach acid production also provides an environment conducive to the overgrowth of anaerobic bacteria in the stomach, which further interferes with vitamin B_{12} absorption (3). Because vitamin B_{12} in supplements is not bound to protein, and because intrinsic factor (IF) is still available, the absorption of supplemental vitamin B_{12} is not reduced as it is in pernicious anemia. Thus, individuals with food-bound vitamin B_{12} malabsorption do not have an increased requirement for vitamin B_{12}; they simply need it in the crystalline form found in fortified foods and dietary supplements.

Other causes of vitamin B_{12} deficiency

Other causes of vitamin B_{12} deficiency include surgical resection of the stomach or portions of the small intestine where receptors for the IF-B_{12} complex are located. Conditions affecting the small intestine, such as malabsorption syndromes (celiac disease and tropical sprue), may also result in vitamin B_{12} deficiency. Because the pancreas provides critical enzymes, as well as calcium required for vitamin B_{12} absorption, pancreatic insufficiency may contribute to vitamin B_{12} deficiency. Since vitamin B_{12} is found only in foods of animal origin, a strict vegetarian (vegan) diet has resulted in cases of vitamin B_{12} deficiency. Moreover, alcoholics may experience reduced intestinal absorption of vitamin B_{12} (2), and individuals with acquired immunodeficiency syndrome (AIDS) appear to be at increased risk of deficiency, possibly related to a failure of the IF-B_{12} receptor to take up the IF-B_{12} complex (3). Further, long-term use of acid-reducing drugs has also been implicated in vitamin B_{12} deficiency (see Drug interactions).

Inherited disorders of vitamin B_{12} absorption

Rare cases of inborn errors of vitamin B_{12} metabolism have been reported in the literature (reviewed in 5). Imerslund-Gräsbeck syndrome is an inherited vitamin B_{12} malabsorption syndrome that causes megaloblastic anemia and neurologic disorders of variable severity in affected subjects. Similar clinical symptoms are found in individuals with hereditary IF deficiency (also called congenital pernicious anemia) in whom the lack of IF results in the defective absorption of vitamin B_{12}. Additionally, mutations affecting vitamin B_{12} transport in the body have been identified (14).

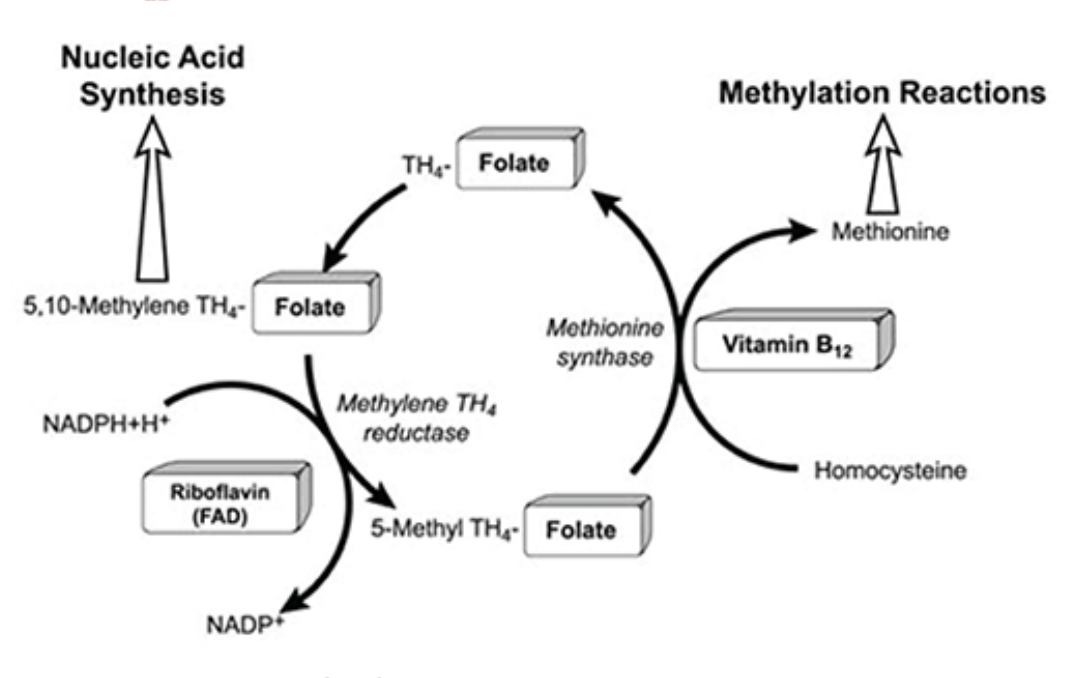
Symptoms of vitamin B_{12} deficiency

Vitamin B_{12} deficiency results in impairment of the activities of vitamin B_{12}-requiring enzymes. Impaired activity of methionine synthase results in elevated homocysteine levels, while impaired activity of L-methylmalonyl-CoA mutase results in increased levels of a metabolite of methylmalonyl-CoA called methylmalonic acid (MMA). While individuals with mild vitamin B_{12} deficiency may not experience symptoms, blood levels of homocysteine and/or MMA may be elevated (15).

Megaloblastic anemia

Diminished activity of methionine synthase in vitamin B_{12} deficiency inhibits the regeneration of tetrahydrofolate (THF) and traps folate in a form that is not usable by the body (**Figure 3**), resulting in symptoms of folate deficiency even in the presence of adequate folate levels. Thus, in both folate and vitamin B_{12} deficiencies, folate is unavailable to participate in DNA synthesis. This impairment of DNA synthesis affects the rapidly dividing cells of the bone marrow earlier than other cells, resulting in the production of large, immature, hemoglobin-poor red blood cells. The resulting anemia is known as megaloblastic anemia and is the symptom for which the disease, pernicious anemia, was named (3). Supplementation with folic acid will provide enough usable folate to restore normal red blood cell formation. However, if vitamin B_{12} deficiency is the cause, it will persist despite the resolution of the anemia. Thus, megaloblastic anemia should not be treated with folic acid until the underlying cause has been determined (16).

Figure 3. Vitamin B_{12} and Nucleic Acid Metabolism



5,10-Methylene tetrahydrofolate (TH_4) is required for the synthesis of nucleic acids, while 5-methyl TH_4 is required for the formation of methionine from homocysteine. Methionine, in the form of S-adenosylmethionine, is required for many biological methylation reactions, including DNA methylation. Methylene TH_4 reductase is a flavin-dependent enzyme required to catalyze the reduction of 5,10-methylene TH_4 to 5-methyl TH_4.

Neurologic symptoms

The neurologic symptoms of vitamin B_{12} deficiency include numbness and tingling of the hands and, more commonly, the feet; difficulty walking; memory loss; disorientation; and dementia with or without mood changes. Although the progression of neurologic complications is generally gradual, such symptoms may not be reversed with treatment of vitamin B_{12} deficiency, especially if they have been present for a long time. Neurologic complications are not always associated with megaloblastic anemia and are the only clinical symptom of vitamin B_{12} deficiency in about 25% of cases (17). Although vitamin B_{12} deficiency is known to damage the myelin sheath covering cranial, spinal, and peripheral nerves, the biochemical processes leading to neurological damage in vitamin B_{12} deficiency are not yet fully understood (18).

Gastrointestinal symptoms

Tongue soreness, appetite loss, and constipation have also been associated with vitamin B_{12} deficiency. The origins of these symptoms are unclear, but they may be related to the stomach inflammation underlying some cases of vitamin B_{12} deficiency and to the progressive destruction of the lining of the stomach (17).

The Recommended Dietary Allowance (RDA)

The RDA for vitamin B_{12} was revised by the Food and Nutrition Board (FNB) of the US Institute of Medicine in 1998 (**Table 1**). Because of the increased risk of food-bound vitamin B_{12} malabsorption in older adults, the FNB recommended that adults over 50 years of age get most of the RDA from fortified food or vitamin B_{12}-containing supplements (17).

Table 1. Recommended Dietary Allowance (RDA) for Vitamin B_{12}

Life Stage	Age	Males (μg/day)	Females (μg/day)
Infants	0-6 months	0.4 (AI)	0.4 (AI)
Infants	7-12 months	0.5 (AI)	0.5 (AI)
Children	1-3 years	0.9	0.9
Children	4-8 years	1.2	1.2
Children	9-13 years	1.8	1.8
Adolescents	14-18 years	2.4	2.4
Adults	19-50 years	2.4	2.4
Adults	51 years and older	2.4*	2.4*
Pregnancy	all ages	-	2.6
Breast-feeding	all ages	-	2.8

*Vitamin B_{12} intake should be from supplements or fortified foods due to the age-related increase in food-bound malabsorption.

Disease Prevention

Cardiovascular disease

As mentioned above, chronic atrophic gastritis and infection by *H. pylori* can cause deficiency in vitamin B_{12} secondary to malabsorption disorders (see Causes of vitamin B_{12} deficiency). However, the occurrence of *H. pylori* infection and chronic atrophic gastritis did not modify the five-year incidence of cardiovascular accidents (stroke and heart attack) or mortality in a large cohort study of nearly 10,000 men and women over 50 years old (19). Yet, vitamin B_{12} status was not assessed in this study, despite the high prevalence of vitamin B_{12} deficiency in older individuals.

Homocysteine and cardiovascular disease

Epidemiological studies indicate that even moderately elevated levels of homocysteine in the blood raise the risk of cardiovascular disease (CVD) (20), though the mechanism by which homocysteine may increase the CVD risk remains the subject of a great deal of research (21). The amount of homocysteine in the blood is regulated by at least three vitamins: folate, vitamin B_6, and vitamin B_{12} (see **Figure 1** above). An early analysis of the results of 12 randomized controlled trials showed that folic acid supplementation (0.5-5 mg/day) had the greatest lowering effect on blood homocysteine levels (25% decrease); co-supplementation with folic acid and vitamin B_{12} (500 μg/day) provided an additional 7% reduction (32% decrease) in blood homocysteine concentrations (22). The results of a sequential supplementation trial in 53 men and women indicated that after folic acid supplementation, vitamin B_{12} became the major determinant of plasma homocysteine levels (23). It is thought that the elevation of homocysteine levels might be partly due to vitamin B_{12} deficiency in individuals over 60 years of age. Two studies found blood methylmalonic acid (MMA) levels to be elevated in more than 60% of elderly individuals with elevated homocysteine levels. In the absence of impaired kidney function, an elevated MMA level in conjunction with elevated homocysteine suggests either a vitamin B_{12} deficiency or a combined vitamin B_{12} and folate deficiency (24). Thus, it appears important to evaluate vitamin B_{12} status, as well as kidney function, in older individuals with elevated homocysteine levels prior to initiating homocysteine-lowering therapy. For more information regarding homocysteine and CVD, see the article on Folate.

Intervention studies

Although increased intake of folic acid and vitamin B_{12} is effective in decreasing homocysteine levels, the combined intervention of these B vitamins did not lower risk for CVD. Indeed, several randomized, placebo-controlled trials have been conducted to determine whether homocysteine-lowering through folic acid, vitamin B_{12}, and vitamin B_6 supplementation reduces the incidence of CVD. A recent meta-analysis of data from 11 trials, including nearly 45,000 participants at risk of CVD, showed that B-vitamin supplementation had no significant effect on risk of myocardial infarction (heart attack) or stroke, nor did it modify the risk of all-cause mortality (25). Other meta-analyses that included patients with chronic kidney disease have confirmed the lack of effect of homocysteine-lowering on risk of myocardial infarction and death. However, stroke risk was significantly reduced by 7%-12% with the B-vitamin supplementation (26, 27). Another meta-analysis of 12 clinical trials measuring flow-mediated vasodilation (FMD; a surrogate marker of vascular health) in response to homocysteine reduction revealed that B-vitamin supplementation was accompanied by an improved FMD in short-term <8 weeks) but not in long-term studies conducted in subjects with preexisting vascular diseases (28). Yet, some of the studies included in these meta-analyses did not use vitamin B_{12}, and folate administration on its own has shown a protective role on vascular function and stroke risk (29). Besides, the high prevalence of malabsorption disorders and vitamin B_{12} deficiency in elderly individuals might warrant the use of higher doses of vitamin B_{12} than those used in these trials (30); in cases of malabsorption, only high-dose oral therapy or intramuscular injections can overcome vitamin B_{12} deficiency (4).

Cancer

Folate is required for synthesis of DNA, and there is evidence that decreased availability of folate results in strands of DNA that are more susceptible to damage. Deficiency of vitamin B_{12} traps folate in a form that is unusable by the body for DNA synthesis. Both vitamin B_{12} and folate deficiencies result in a diminished capacity for methylation reactions (see **Figure 3** above). Thus, vitamin B_{12} deficiency may lead to an elevated rate of DNA damage and altered methylation of DNA, both of which are important risk factors for cancer. A series of studies in young adults and older men indicated that increased levels of homocysteine and decreased levels of vitamin B_{12} in the blood were associated with a biomarker of chromosome breakage in white blood cells (reviewed in 31). In a double-blind, placebo-controlled study, the same biomarker of chromosome breakage was minimized in young adults who were supplemented with 700 μg of folic acid and 7 μg of vitamin B_{12} daily in cereal for two months (32).

Breast cancer

A case-control study compared prediagnostic levels of serum folate, vitamin B_6, and vitamin B_{12} in 195 women later diagnosed with breast cancer and 195 age-matched, cancer-free women. Among postmenopausal women, the association between blood levels of vitamin B_{12} and breast cancer suggested a threshold effect. The risk of breast cancer was more than doubled in women with serum vitamin B_{12} levels in the lowest quintile compared to women in the four highest quintiles (33). However, the meta-analysis of this study with three additional case-control studies found no protection associated with high compared to low vitamin B_{12} serum levels (34). A case-control study in Mexican women (475 cases and 1,391 controls) reported that breast cancer risk for women in the highest quartile of vitamin B_{12} intake (7.3-7.7 μg/day) was 68% lower than those in the lowest quartile (2.6 μg/day). Stratification of the data revealed that the inverse association between dietary vitamin B_{12} intake and breast cancer risk was stronger in postmenopausal women compared to premenopausal women, though both associations were statistically significant. Moreover, among postmenopausal women, the apparent protection conferred by folate was only observed in women with the highest vitamin B_{12} quartiles of intake (35). However, more recent case-control and prospective cohort studies have reported weak to no risk reduction with vitamin B_{12} intakes in different populations, including Hispanic, African American and European American women (36, 37). A meta-analysis of seven case-control and seven prospective cohort studies concluded that the risk of breast cancer was not modified by high versus low vitamin B_{12} intakes (34). There was no joint association between folate and vitamin B_{12} intakes and breast cancer risk. Presently, there is little evidence to suggest a relationship between vitamin B_{12} status and breast cancer. In addition, results from observational studies are not consistently in support of an association between high dietary folate intakes and reduced risk for breast cancer (see the article on Folate). There is a need to evaluate the effect of folate and vitamin B_{12} supplementation in well-controlled, randomized, clinical trials, while considering various factors that modify breast cancer risk, such as menopausal status, ethnicity, and alcohol intake.

Neural tube defects

Neural tube defects (NTD) may result in anencephaly or spina bifida, which are mostly fatal congenital malformations of the central nervous system. The defects arise from failure of embryonic neural tube to close, which occurs between the 21st and 28th days after conception, a time when many women are unaware of their pregnancy (38). Randomized controlled trials have demonstrated 60% to 100% reductions in NTD cases when women consumed folic acid supplements in addition to a varied diet during the month before and the month after conception. Increasing evidence indicates that the homocysteine-lowering effect of folic acid plays a critical role in reducing the risk of NTD (39). Homocysteine may accumulate in the blood when there is inadequate folate and/or vitamin B_{12} for effective functioning of the methionine synthase enzyme. Decreased vitamin B_{12} levels and elevated homocysteine concentrations have been found in the blood and amniotic fluid of pregnant women at high risk of NTD (40). The recent meta-analysis of 12 case-control studies, including 567 mothers with current or prior NTD-affected pregnancy and 1,566 unaffected mothers, showed that low maternal vitamin B_{12} status was associated with an increased risk of NTD (41). Yet, whether vitamin B_{12} supplementation may be beneficial in the prevention of NTD has not been evaluated (42).

Cognitive decline, dementia, and Alzheimer's disease

The occurrence of vitamin B_{12} deficiency prevails in the elderly population and has been frequently associated with Alzheimer's disease (reviewed in 43). One study found lower vitamin B_{12} levels in the cerebrospinal fluid of patients with Alzheimer's disease than in patients with other types of dementia, though blood levels of vitamin B_{12} did not differ (44). The reason for the association of low vitamin B_{12} status with Alzheimer's disease is not clear. Vitamin B_{12} deficiency, like folate deficiency, may lead to decreased synthesis of methionine and S-adenosylmethionine (SAM), thereby adversely affecting methylation reactions. Methylation reactions are essential for the metabolism of components of the myelin sheath of nerve cells as well as for synthesis of neurotransmitters (18). Other metabolic implications of vitamin B_{12} deficiency include the accumulation of homocysteine and methylmalonic acid, which might contribute to the neuropathologic features of dementia (43).

Observational studies

A large majority of cross-sectional and prospective cohort studies have associated elevated homocysteine concentrations with measures of poor cognitive scores and increased risk of dementia, including Alzheimer's disease (reviewed in 45). A case-control study of 164 patients with dementia of Alzheimer's type included 76 cases in which the diagnosis of Alzheimer's disease was confirmed by examination of brain cells after death. Compared to 108 control subjects without evidence of dementia, subjects with dementia of Alzheimer's type and confirmed Alzheimer's disease had higher blood homocysteine levels and lower blood levels of folate and vitamin B_{12}. Measures of general nutritional status indicated that the association of increased homocysteine levels and diminished vitamin B_{12} status with Alzheimer's disease was not due to dementia-related malnutrition (46). In a sample of 1,092 men and women without dementia followed for an average of 10 years, those with higher plasma homocysteine levels at baseline had a significantly higher risk of developing Alzheimer's disease and other types of dementia. Specifically, those with plasma homocysteine levels greater than 14 μmol/L had nearly double the risk of developing Alzheimer's disease (47). A study in 650 elderly men and women reported that the risk of elevated plasma homocysteine levels was significantly higher in those with lower cognitive function scores (48). A prospective study in 816 elderly men and women reported that those with hyperhomocysteinemia (homocysteine levels >15 μmol/L) had a significantly higher risk of developing Alzheimer's disease or dementia. Although raised homocysteine levels might be partly due to a poor vitamin B_{12} status, the latter was not related to risk of Alzheimer's disease or dementia in this study (49).

A recent systematic review of 35 prospective cohort studies assessing the association between vitamin B_{12} status and cognitive deterioration in older individuals with or without dementia at baseline did not support a relationship between vitamin B_{12} serum concentrations and cognitive decline, dementia, or Alzheimer's disease (50). Nevertheless, studies utilizing more sensitive biomarkers of vitamin B_{12} status, including measures of holo-transcobalamin (holo-TC; a vitamin B_{12} carrier) and methylmalonic acid, showed more consistent results and a trend toward associations between poor vitamin B_{12} status and faster cognitive decline and risk of Alzheimer's disease (51-55). Besides, it cannot be excluded that the co-occurrence of potential confounders like elevated homocysteine level and poor folate status might mitigate the true contribution of vitamin B_{12} status to cognitive functioning (45).

Intervention studies

High-dose B-vitamin supplementation has been proven effective for treating hyperhomocysteinemia in elderly individuals with or without cognitive impairment. However, homocysteine-lowering trials have produced equivocal results regarding the prevention of cognitive deterioration in this population. A systematic review and meta-analysis of 18 randomized, placebo-controlled trials examining the effect of B-vitamin supplementation did not find that the decrease in homocysteine level prevented or delayed cognitive decline among older subjects (56). A more recent randomized, double-blind, placebo-controlled clinical trial in 900 older individuals at high risk of cognitive impairment found that daily supplementation of 400 μg of folic acid and 100 μg of vitamin B_{12} for two years significantly improved measures of immediate and delayed memory and slowed the rise in plasma homocysteine concentrations (57). However, supplemented subjects had no reduction in homocysteine concentrations compared to baseline, nor did they perform better in processing speed tests compared to placebo. Another two-year, randomized, placebo-controlled study in elderly adults reported that a daily regimen of 800 μg of folic acid, 500 μg of vitamin B_{12}, and 20 mg of vitamin B_6 significantly reduced the rate of brain atrophy compared to placebo treatment (0.5% vs. 3.7%). Interestingly, a greater benefit was seen in those with high compared to low homocysteine concentrations at baseline, suggesting the importance of lowering homocysteine levels in prevention of brain atrophy and cognitive decline (58, 59). The authors attributed the changes in homocysteine levels primarily to vitamin B_{12} (59). Finally, the most recent randomized, double blind, placebo-controlled trial in over 2,500 individuals who suffered a stroke showed that the normalization of homocysteine concentrations by B-vitamin supplementation (2 mg of folic acid, 500 μg of vitamin B_{12}, and 25 mg of vitamin B_6) did not improve cognitive performance or decrease incidence of cognitive decline compared to placebo (60). Currently, there is a need for larger trials to evaluate the effect of B-vitamin supplementation on long-term outcomes, such as the incidence of Alzheimer's disease.

Depression

Observational studies have found as many as 30% of patients hospitalized for depression are deficient in vitamin B_{12} (61). A cross-sectional study of 700 community-living, physically disabled women over the age of 65 found that vitamin B_{12}-deficient women were twice as likely to be severely depressed as non-deficient women (62). A population-based study in 3,884 elderly men and women with depressive disorders found that those with vitamin B_{12} deficiency were almost 70% more likely to experience depression than those with normal vitamin B_{12} status (63). The reasons for the relationship between vitamin B_{12} deficiency and depression are not clear but may involve a shortage in S-adenosylmethionine (SAM). SAM is a methyl group donor for numerous methylation reactions in the brain, including those involved in the metabolism of neurotransmitters whose deficiency has been related to depression (64). Severe vitamin B_{12} deficiency in a mouse model showed dramatic alterations in the level of DNA methylation in the brain, which might lead to neurologic impairments (65). This hypothesis is supported by several studies that have shown supplementation with SAM improves depressive symptoms (66-69).

Increased homocysteine level is another nonspecific biomarker of vitamin B_{12} deficiency that has been linked to depressive symptoms in the elderly (70). However, in a recent cross-sectional study conducted in 1,677 older individuals, higher vitamin B_{12} plasma levels, but not changes in homocysteine concentrations, were correlated with a lower prevalence of depressive symptoms (71). Few studies have examined the relationship of vitamin B_{12} status, homocysteine levels, and the development of depression over time. In a randomized, placebo-controlled, intervention study with over 900 older participants experiencing psychological distress, daily supplementation with folic acid (400 μg) and vitamin B_{12} (100 μg) for two years did not reduce the occurrence of symptoms of depression despite significantly improving blood folate, vitamin B_{12}, and homocysteine levels compared to placebo (72). However, in a long-term randomized, double-blind, placebo-controlled study among sufferers of cerebrovascular accidents at high risk of depression, daily supplementation with 2 mg of folic acid, 25 mg of vitamin B_6, and 500 μg vitamin B_{12} significantly lowered the risk of major depressive episodes during a seven-year follow-up period compared to placebo (73). Although it cannot yet be determined whether vitamin B_{12} deficiency plays a causal role in depression, it may be beneficial to screen for vitamin B_{12} deficiency in older individuals as part of a medical evaluation for depression.

Osteoporosis

High homocysteine levels may affect bone remodeling by increasing bone resorption (breakdown), decreasing bone formation, and reducing bone blood flow. Another proposed mechanism involves the binding of homocysteine to the collagenous matrix of bone, which may modify collagen properties and reduce bone strength (reviewed in 74). Alterations of bone biomechanical properties can contribute to osteoporosis and increase the risk of fractures in the elderly. Since vitamin B_{12} is a determinant of homocysteine metabolism, it was suggested that the risk of osteoporotic fractures in older subjects might be enhanced by vitamin B_{12} deficiency. A meta-analysis of four observational studies, following a total of 7,475 older individuals for 3 to 16 years, found a weak association between an elevation in vitamin B_{12} of 50 picomoles/L in blood and a reduction in fracture risk (75). A randomized, placebo-controlled trial in 559 elderly individuals with low serum levels of folate and vitamin B_{12} and at increased risk of fracture evaluated the combined supplementation of very high doses of folic acid (5 mg/day) and vitamin B_{12} (1.5 mg/day). The two-year study found that the supplementation improved B-vitamin status, decreased homocysteine concentrations, and reduced risk of total fractures compared to placebo (76). However, a multicenter study in 5,485 subjects with cardiovascular disease or diabetes mellitus showed that daily supplementation with folic acid (2.5 mg), vitamin B_{12} (1 mg), and vitamin B_6 (50 mg) lowered homocysteine concentrations but had no effect on fracture risk compared to placebo (77). Another small, randomized, double-blind trial in 93 individuals with low vitamin D status found no additional benefit of B-vitamin supplementation (50 mg/day of vitamin B_6, 0.5 mg/day of folic acid, and 0.5 mg/day of vitamin B_{12}) on markers of bone health over a one-year period beyond that associated with vitamin D and calcium supplementation. Yet, the short length of the study did not permit a conclusion on whether the lowering of homocysteine through B-vitamin supplementation could have long-term benefits on bone strength and fracture risk (78). A large intervention study conducted in older people with no preexisting conditions is under way to evaluate the effect of B-vitamin supplementation on markers of bone health and incidence of fracture; this trial might clarify whether B vitamins could have a protective effect on bone health in the elderly population (79).

Sources

Food sources

Only bacteria can synthesize vitamin B_{12} (80). Vitamin B_{12} is present in animal products, such as meat, poultry, fish (including shellfish), and to a lesser extent dairy products and eggs (1). Fresh pasteurized milk contains 0.9 μg per cup and is an important source of vitamin B_{12} for some vegetarians (17). Those strict vegetarians who eat no animal products (vegans) need supplemental vitamin B_{12} to meet their requirements. Recent analyses revealed that some plant-source foods, such as certain fermented beans and vegetables and edible algae and mushrooms, contain substantial amounts of bioactive vitamin B_{12} (81). Together with B-vitamin fortified food and supplements, these foods may contribute, though modestly, to prevent vitamin B_{12} deficiency in individuals consuming vegetarian diets. Also, individuals over the age of 50 should obtain their vitamin B_{12} in supplements or fortified foods (e.g., fortified cereals) because of the increased likelihood of food-bound vitamin B_{12} malabsorption with increasing age.

Most people do not have a problem obtaining the RDA of 2.4 μg/day of vitamin B_{12} in food. According to a US national survey, the average dietary intake of vitamin B_{12} is 5.4 μg/day for adult men and 3.4 μg/day for adult women. Adults over the age of 60 had an average dietary intake of 4.8 μg/day (42). However, consumption of any type of vegetarian diet dramatically increases the prevalence of vitamin B_{12} deficiency in individuals across all age groups (82). Some foods with substantial amounts of vitamin B_{12} are listed in **Table 2**, along with their vitamin B_{12} content in micrograms (μg). For more information on the nutrient content of specific foods, search USDA's FoodData Central.

Table 2. Some Food Sources of Vitamin B_{12}

Food	Serving	Vitamin B_{12} (μg)
Clams (steamed)	3 ounces	84.1
Mussels (steamed)	3 ounces	20.4
Mackerel (Atlantic, cooked, dry-heat)	3 ounces*	16.1
Crab (Alaska king, steamed)	3 ounces	9.8
Beef (lean, plate steak, cooked, grilled)	3 ounces	6.9
Salmon (chinook, cooked, dry-heat)	3 ounces	2.4
Rockfish (cooked, dry-heat)	3 ounces	1.0
Milk (skim)	8 ounces	0.9
Turkey (cooked, roasted)	3 ounces	0.8
Brie (cheese)	1 ounce	0.5
Egg (poached)	1 large	0.4
Chicken (light meat, cooked, roasted)	3 ounces	0.3

*A three-ounce serving of meat or fish is about the size of a deck of cards.

Supplements

Cyanocobalamin is the principal form of vitamin B_{12} used in oral supplements, but methylcobalamin is also available as a supplement. Cyanocobalamin is available by prescription in an injectable form and as a nasal gel for the treatment of pernicious anemia. Over-the-counter preparations containing cyanocobalamin include multivitamins, vitamin B-complex supplements, and single-nutrient, vitamin B_{12} supplements (83).

Safety

Toxicity

No toxic or adverse effects have been associated with large intakes of vitamin B_{12} from food or supplements in healthy people. Doses as high as 2 mg (2,000 μg) daily by mouth or 1 mg monthly by intramuscular (IM) injection have been used to treat pernicious anemia without significant side effects (84). When high doses of vitamin B_{12} are given orally, only a small percentage can be absorbed, which may explain the low toxicity (4). Because of the low toxicity of vitamin B_{12}, no tolerable upper intake level (UL) has been set by the US Food and Nutrition Board (17).

Drug interactions

A number of drugs reduce the absorption of vitamin B_{12}. Proton-pump inhibitors (e.g., omeprazole and lansoprazole), used for therapy of Zollinger-Ellison syndrome and gastroesophageal reflux disease (GERD), markedly decrease stomach acid secretion required for the release of vitamin B_{12} from food but not from supplements. Long-term use of proton-pump inhibitors has been found to decrease blood vitamin B_{12} levels. However, vitamin B_{12} deficiency does not generally develop until after at least three years of continuous therapy (85, 86). Another class of gastric acid inhibitors known as histamine$_2$ (H_2)-receptor antagonists (e.g., cimetidine, famotidine, and ranitidine), often used to treat peptic ulcer disease, has also been found to decrease the absorption of vitamin B_{12} from food. It is not clear whether the long-term use of H_2-receptor antagonists could cause overt vitamin B_{12} deficiency (87, 88). Individuals taking drugs that inhibit gastric acid secretion should consider taking vitamin B_{12} in the form of a supplement because gastric acid is not required for its absorption. Other drugs found to inhibit vitamin B_{12} absorption from food include cholestyramine (a bile acid-binding resin used in the treatment of high cholesterol), chloramphenicol and neomycin (antibiotics), and colchicine (medicine for gout treatment). Metformin, a medication for individuals with type 2 diabetes, was found to decrease vitamin B_{12} absorption by tying up free calcium required for absorption of the IF-B_{12} complex (89). However, the clinical significance of this is unclear (90). It is not known whether calcium supplementation can reverse vitamin B_{12} malabsorption; therefore, calcium supplementation is not currently prescribed for the prevention or treatment of metformin-induced vitamin B_{12} deficiency (91). Previous reports that megadoses of vitamin C destroy vitamin B_{12} have not been supported (92) and may have been an artifact of the assay used to measure vitamin B_{12} levels (17).

Nitrous oxide, a commonly used anesthetic, oxidizes and inactivates vitamin B_{12}, thus inhibiting both of the vitamin B_{12}-dependent enzymes, and can produce many of the clinical features of vitamin B_{12} deficiency, such as megaloblastic anemia or neuropathy. Since nitrous oxide is commonly used for surgery in the elderly, some experts feel vitamin B_{12} deficiency should be ruled out prior to its use (6, 15).

Large doses of folic acid given to an individual with an undiagnosed vitamin B_{12} deficiency could correct megaloblastic anemia without correcting the underlying vitamin B_{12} deficiency, leaving the individual at risk of developing irreversible neurologic damage (17). For this reason, the Food and Nutrition Board of the US Institute of Medicine advises that all adults limit their intake of folic acid (supplements and fortification) to 1,000 µg (1 mg) daily.

Linus Pauling Institute Recommendation

A varied diet should provide enough vitamin B_{12} to prevent deficiency in most individuals 50 years of age and younger. Strict vegetarians and women planning to become pregnant should take a multivitamin supplement daily or eat fortified cereal, which would ensure a daily intake of 6 to 30 µg of vitamin B_{12} in a form that is easily absorbed. Higher doses of vitamin B_{12} supplements are recommended for patients taking medications that interfere with its absorption (see Drug interactions).

Older adults (>50 years)

Because vitamin B_{12} malabsorption and vitamin B_{12} deficiency are more common in older adults, the Linus Pauling Institute recommends that adults older than 50 years take 100 to 400 µg/day of supplemental vitamin B_{12}.

Summary

- Vitamin C, also known as L-ascorbic acid, is a water-soluble vitamin. Unlike most mammals and other animals, humans do not have the ability to synthesize vitamin C and must obtain it from the diet. *(More information)*
- Vitamin C is an essential cofactor in numerous enzymatic reactions, e.g., in the biosynthesis of collagen, carnitine, and neuropeptides, and in the regulation of gene expression. It is also a potent antioxidant. *(More information)*
- Prospective cohort studies indicate that higher vitamin C status, assessed by measuring circulating vitamin C, is associated with lower risks of hypertension, coronary heart disease, and stroke. *(More information)*
- There is some evidence to suggest that vitamin C may be a useful adjunct to conventional medical practice to reduce myocardial injury and arrhythmia following a cardiac procedure or surgery in patients with cardiovascular disease. *(More information)*
- There are insufficient data to suggest a link between vitamin C status and the risk of developing a given type of cancer. Most observational studies examining vitamin C intake in relation to cancer incidence have found no association. Randomized controlled trials have reported no effect of vitamin C supplementation on cancer risk. *(More information)*
- Current evidence of the efficacy of intravenous vitamin C in cancer patients is limited to observational studies, uncontrolled interventions, and case reports. There is a need for large, longer-duration phase II clinical trials that test the efficacy of intravenous vitamin C in cancer progression and overall survival. *(More information)*
- Overall, regular use of vitamin C supplements shortens the duration of the common cold but does not reduce the risk of becoming ill. Taking supplements once cold symptoms have already begun has no proven benefits. *(More information)*
- Vitamin C supplements are available in many forms, but there is little scientific evidence that any one form is better absorbed or more effective than another. *(More information)*
- There is no scientific evidence that large amounts of vitamin C (up to 10 grams [g]/day in adults) exert any adverse or toxic effects. An upper intake level of 2 g/day is recommended in order to prevent some adults from experiencing diarrhea and gastrointestinal disturbances. *(More information)*
- Supplemental vitamin C increases urinary oxalate concentrations, but whether an increase in urinary oxalate elevates the risk for kidney stones is not yet known. Those predisposed for kidney stone formation may consider avoiding high-dose (≥1 g/day) vitamin C supplementation. *(More information)*

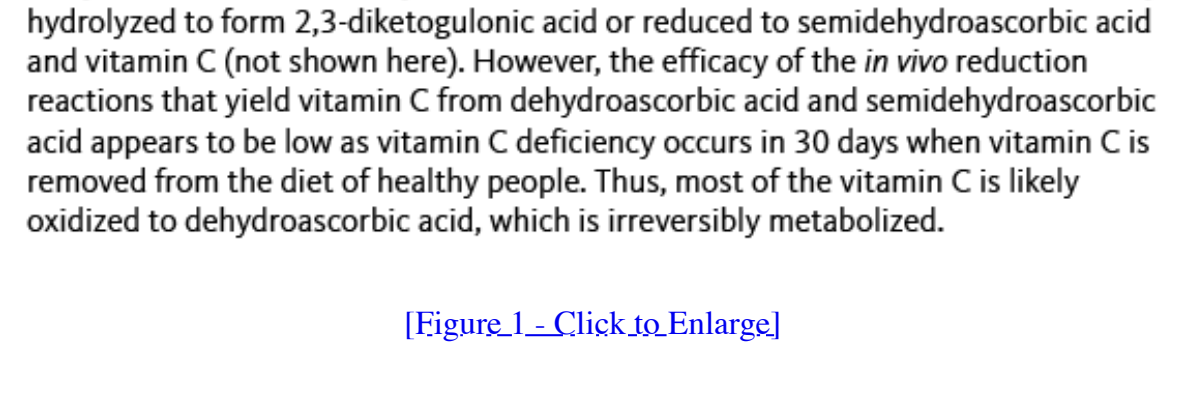
Function

Vitamin C (L-ascorbic acid) is a potent reducing agent, meaning that it readily donates electrons to recipient molecules (**Figure 1**). Related to this oxidation-reduction (redox) potential, two major functions of vitamin C are as an antioxidant and as an enzyme cofactor (1).

Vitamin C is the primary water-soluble, non-enzymatic antioxidant in plasma and tissues. Even in small amounts, vitamin C can protect indispensable molecules in the body, such as proteins, lipids (fats), carbohydrates, and nucleic acids (DNA and RNA), from damage by free radicals and reactive oxygen species (ROS) that are generated during normal metabolism, by active immune cells, and through exposure to toxins and pollutants (e.g., certain chemotherapy drugs and cigarette smoke). Vitamin C also participates in redox recycling of other important antioxidants; for example, vitamin C is known to regenerate vitamin E from its oxidized form (see the article on Vitamin E).

The role of vitamin C as a cofactor is also related to its redox potential. By maintaining enzyme-bound metals in their reduced forms, vitamin C assists mixed-function oxidases in the synthesis of several critical biomolecules (1). These enzymes are either monooxygenases or dioxygenases (see **Table 1**). Symptoms of vitamin C deficiency, such as poor wound healing and lethargy, likely result from the impairment of these vitamin C-dependent enzymatic reactions leading to the insufficient synthesis of collagen, carnitine, and catecholamines (see Deficiency). Moreover, several dioxygenases involved in the regulation of gene expression and the maintenance of genome integrity require vitamin C as a cofactor. Indeed, research has recently uncovered the crucial role played by enzymes, such as the TET dioxygenases and Jumonji domain-containing histone demethylases, in the fate of cells and tissues (see **Table 1**). These enzymes contribute to the epigenetic regulation of gene expression by catalyzing reactions involved in the demethylation of DNA and histones.

Figure 1. Vitamin C



Vitamin C (L-ascorbic acid) is an electron donor. Vitamin C can sequentially donate two electrons. Vitamin C can donate electrons to reactive free radicals, which then become reduced. The loss of one electron results in vitamin C being oxidized to the ascorbate free radical, which is relatively unreactive compared to other free radicals. The ascorbate free radical can be reduced to vitamin C by gaining one electron or be further oxidized to dehydroascorbic acid by losing another electron. Dehydroascorbic acid is only stable for a few minutes and is then either irreversibly hydrolyzed to form 2,3-diketogulonic acid or reduced to semidehydroascorbic acid and vitamin C (not shown here). However, the efficacy of the *in vivo* reduction reactions that yield vitamin C from dehydroascorbic acid and semidehydroascorbic acid appears to be low as vitamin C deficiency occurs in 30 days when vitamin C is removed from the diet of healthy people. Thus, most of the vitamin C is likely oxidized to dehydroascorbic acid, which is irreversibly metabolized.

[Figure 1 - Click to Enlarge]

Table 1. Enzymes Requiring Vitamin C as a Cofactor in Mammals (1, 2)

Enzymes*	Functions
Monooxygenases	
Dopamine β-monooxygenase	Norepinephrine (Noradrenaline) biosynthesis
Peptidyl-glycine α-amidating monooxygenase	Amidation of peptide hormones
Dioxygenases	
3 Prolyl 4-hydroxylase isoenzymes	Collagen hydroxylation
3 Prolyl 3-hydroxylase isoenzymes	Collagen hydroxylation
3 Lysyl hydroxylase isoenzymes	Collagen hydroxylation
4 Hypoxia-inducible factor (HIF) isoenzymes	HIF hydroxylation
Trimethyllysine hydroxylase	Carnitine biosynthesis
γ-Butyrobetaine hydroxylase	Carnitine biosynthesis
4-Hydroxyphenylpyruvate dioxygenase	Tyrosine metabolism
Ten-eleven translocation (TET) family of dioxygenases	Demethylation of DNA
Jumonji domain-containing histone demethylases	Demethylation of histones
*Monooxygenases catalyze the hydroxylation of one substrate, whereas dioxygenases catalyze a reaction that couples the hydroxylation of a specific substrate with the conversion (decarboxylation) of α-ketoglutarate into succinate.	

The capacity of vitamin C to influence the methylation status of DNA and histones in mammalian cells supports a role for the vitamin in health and disease beyond what was previously understood, in particular by safeguarding genome integrity (3, 4).

Role in immunity

Vitamin C affects several components of the human immune system *in vitro*; for example, vitamin C has been shown to stimulate both the production (5-9) and function (10, 11) of leukocytes (white blood cells), especially neutrophils, lymphocytes, and phagocytes. Specific measures of functions stimulated by vitamin C include cellular motility (10), chemotaxis (10, 11), and phagocytosis (11). Neutrophils, mononuclear phagocytes, and lymphocytes accumulate vitamin C to high concentrations, which can protect these cell types from oxidative damage (12-14). In response to invading microorganisms, phagocytic leukocytes release non-specific toxins, such as superoxide radicals, hypochlorous acid ("bleach"), and peroxynitrite; these reactive oxygen species kill pathogens and, in the process, can damage the leukocytes themselves (15). Vitamin C, through its antioxidant functions, has been shown to protect leukocytes from self-inflicted oxidative damage (14). Phagocytic leukocytes also produce and release cytokines, including interferons, which have antiviral activity (16). Vitamin C has been shown to increase interferon production *in vitro* (17). Additional studies have reported that vitamin C enhances the chemotactic and microbial killing capacities of neutrophils and stimulates the proliferation and differentiation of B- and T-lymphocytes (reviewed in 18).

It is widely thought by the general public that vitamin C boosts immune function, yet human studies published to date are conflicting. Disparate results are likely due to study design issues, often linked to a lack of understanding of vitamin C pharmacokinetics and requirements (19, 20).

Finally, vitamin C increases the bioavailability of iron from foods by enhancing intestinal absorption of non-heme iron (see the article on Iron) (21).

Bioavailability

Depletion-repletion pharmacokinetic experiments demonstrated that plasma vitamin C concentration is tightly controlled by three primary mechanisms: intestinal absorption, tissue transport, and renal reabsorption (22). In response to increasing oral doses of vitamin C, plasma vitamin C concentration rises steeply at intakes between 30 and 100 mg/day. Plasma concentrations of ascorbate reach steady-state at concentrations between 60 and 80 micromoles/L (µmol/L). This is typically observed at doses between 200 to 400 mg/day in healthy young adults, with some degree of individual variation (23, 24).

One hundred percent absorption efficiency is observed when ingesting vitamin C at doses up to 200 mg at a time. Higher doses (>500 mg) result in fractionally less vitamin C being absorbed as the dose increases. Once plasma vitamin C concentrations reach saturation, additional vitamin C is largely excreted in the urine. Notably, intravenous administration of vitamin C bypasses absorptive control in the intestine such that very high concentrations of vitamin C can be achieved in the plasma; within a few hours, renal excretion restores vitamin C to baseline plasma concentrations (see Cancer Treatment) (25).

While plasma vitamin C concentration reflects recent dietary intake, leukocyte (white blood cell) vitamin C is thought to be an indicator of body stores. However, leukocyte vitamin C concentration does not accurately reflect vitamin C in several tissues and may specifically underestimate vitamin C uptake into skeletal muscle (26). Yet, plasma concentrations of vitamin C ≥50 µmol/L are sufficient to saturate muscle tissue vitamin C.

There is also some limited evidence suggesting that individuals who carry certain polymorphisms in genes involved in vitamin C transport and detoxification mechanisms may have lower plasma vitamin C concentrations even with high vitamin C intakes (see also Vascular complications of diabetes mellitus) (reviewed in 27).

Due to the pharmacokinetics and tight regulation of plasma vitamin C, supplementation with vitamin C will have variable effects in vitamin C-replete (plasma concentrations near saturation) versus sub-optimal (plasma concentrations <50 µmol/L), marginally deficient (plasma concentrations <23 µmol/L), or severely deficient (plasma concentrations <11 µmol/L) individuals (28). Scientific studies investigating vitamin C efficacy to prevent or treat disease need to assess baseline vitamin C status before embarking on an intervention or statistical analysis (22, 29-31).

For a more detailed discussion on the bioavailability of different forms of vitamin C, see the article, The Bioavailability of Different Forms of Vitamin C.

Deficiency

Severe vitamin C deficiency has been known for many centuries as the potentially fatal disease, scurvy. By the late 1700s, the British navy was aware that scurvy could be cured by eating oranges or lemons, even though vitamin C would not be isolated until the early 1930s. Symptoms of scurvy include subcutaneous bleeding, poor wound closure, and bruising easily, hair and tooth loss, and joint pain and swelling. Such symptoms appear to be related to the weakening of blood vessels, connective tissue, and bone, which all contain collagen. Early symptoms of scurvy like fatigue may result from diminished levels of carnitine, which is needed to derive energy from fat, or from decreased synthesis of the catecholamine norepinephrine (see Function). Scurvy is rare in developed countries because it can be prevented by as little as 10 mg of vitamin C daily (32). However, cases have occurred in children and the elderly on very restricted diets (33, 34).

The Recommended Dietary Allowance (RDA)

The recommended dietary allowance (RDA) for vitamin C is based on the amount of vitamin C intake necessary to maintain neutrophil vitamin C concentration with minimal urinary excretion of vitamin C and is proposed to provide sufficient antioxidant protection (**Table 2**) (35). The recommended intake for smokers is 35 mg/day higher than for nonsmokers, because smokers are under increased oxidative stress from the toxins in cigarette smoke and generally have lower blood concentrations of vitamin C (36).

Table 2. Recommended Dietary Allowance (RDA) for Vitamin C

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	40 (AI)	40 (AI)
Infants	7-12 months	50 (AI)	50 (AI)
Children	1-3 years	15	15
Children	4-8 years	25	25
Children	9-13 years	45	45
Adolescents	14-18 years	75	65
Adults	19 years and older	90	75
Smokers	19 years and older	125	110
Pregnancy	18 years and younger	-	80
Pregnancy	19 years and older	-	85
Breast-feeding	18 years and younger	-	115
Breast-feeding	19 years and older	-	120

Disease Prevention

The amount of vitamin C required to help prevent chronic disease is higher than the amount required for prevention of scurvy. Information regarding vitamin C and the prevention of chronic disease is based on both observational prospective cohort studies and randomized controlled trials (29, 37). Prospective cohort studies can examine the incidence of a specific disease in relation to vitamin C intake or body status in a cohort of participants who are followed over time. In contrast, trials are intervention studies that can establish a causal relationship between an exposure and an outcome, e.g., by evaluating the effect of vitamin C supplementation on the incidence of chronic disease in participants randomly assigned to receive either vitamin C or placebo for a given length of time.

Cardiovascular disease

Endothelial dysfunction

Endothelial dysfunction is considered to be an early step in the development of atherosclerosis. Alterations in the structure and function of the vascular endothelium that lines the inner surface of all blood vessels are associated with the loss of normal nitric oxide-mediated endothelium-dependent vasodilation. Endothelial dysfunction results in widespread vasoconstriction and coagulation abnormalities. The measurement of brachial artery flow-mediated dilation (FMD) is often used as a functional marker of endothelial function; FMD values are inversely correlated with the risk of future cardiovascular events (38). A 2014 meta-analysis of 44 randomized controlled trials in subjects with or without chronic diseases summarized the effect of supplemental vitamin C on endothelial function by measuring FMD (19 studies), assessing forearm blood flow (20 studies), or by pulse wave analysis (5 trials) (39). Short-term supplementation with vitamin C was found to reduce endothelial dysfunction in subjects with heart failure, atherosclerosis, or diabetes mellitus, but it had no effect in those with hypertension. Vitamin C also limited endothelial dysfunction that was experimentally induced in healthy volunteers (39). Improved endothelial function was observed with daily vitamin C doses above 500 mg (39).

Hypertension

Hypertension is a major risk factor for cardiovascular disease, including coronary heart disease, stroke, and atrial fibrillation. An analysis that combined data from three, large, independent prospective cohorts, (1) Nurses' Health Study 1 (NHS1; 88,540 women, median age 49 years); (2) Nurses' Health Study 2 (NHS2; 97,315 women, median age 36 years); and (3) Health Professionals Follow-up Study (HPFS; 37,375 men, median age 52 years), found no association between the level of vitamin C intake and risk of developing hypertension (40). On the other hand, when plasma vitamin C concentration was measured, cross-sectional studies have consistently indicated an inverse relationship between plasma vitamin C concentration and blood pressure in both men and women (41-43). A 15-year follow-up of about 2,500 participants in the Coronary Artery Risk Development in Young Adults (CARDIA) study found that higher plasma vitamin C and a higher diet quality score were independently associated with a reduced risk of developing hypertension (44). Interestingly, there was no relationship between diet score and risk of hypertension in those with the lowest plasma vitamin C, and plasma vitamin C was positively associated with risk of hypertension in those with low diet scores (44).

A meta-analysis of 29 small randomized controlled trials of short durations (median duration, 8 weeks) in 1,407 participants (10 to 120 subjects per trial; including both normotensive and hypertensive subjects) found that daily supplementation with 60 to 4,000 mg of vitamin C (median dose, 500 mg) reduced systolic blood pressure by 3.84 mm Hg and diastolic blood pressure by 1.48 mm Hg (45). Good quality long-term trials are needed to examine whether the anti-hypertensive effect of vitamin C is sustained over time and eventually results in a reduced risk of cardiovascular events.

It is important for individuals with significantly elevated blood pressure not to rely on vitamin C supplementation alone to reduce their hypertension. They should instead seek or continue treatment with anti-hypertensive medication and make dietary and lifestyle changes in consultation with their health care provider.

Cardiovascular disease risk

Coronary heart disease (CHD) is characterized by the buildup of plaque inside the arteries that supply blood to the heart (atherosclerosis). Over years of buildup and accumulated damage to the coronary arteries, CHD may culminate in a myocardial infarction or heart attack. Many prospective cohort studies have examined the relationship between vitamin C intake from diet and supplements and CHD risk, the results of which have been pooled and analyzed in two separate analyses (46, 47). In 2004, a pooled analysis of nine prospective cohort studies found that supplemental vitamin C intake (≥400 mg/day for a mean of 10 years), but not dietary vitamin C intake, was inversely associated with CHD risk (46). Conversely, a 2008 meta-analysis of 14 cohort studies concluded that dietary, but not supplemental, vitamin C intake was inversely related to CHD risk (47). The most recent large prospective cohort study found an inverse association between dietary vitamin C intake and CHD mortality in Japanese women, but not in men (48). In spite of the variable association depending on source, these analyses indicate an overall inverse association between higher vitamin C intakes and CHD risk.

Limitations inherent to dietary assessment methodology, such as recall bias, measurement error, and residual confounding, may account for some of the inconsistent associations between vitamin C intake and CHD risk. In order to overcome such limitations, some prospective studies measured plasma or serum concentrations of vitamin C as a more reliable index of vitamin C intake and biomarker of body vitamin C status.

The European Investigation into Cancer and Nutrition (EPIC)-Norfolk prospective cohort study investigated the relationship between vitamin C status and incident heart failure in healthy adults (9,187 men and 11,112 women, aged 58.1+/-9.2 years) (49). After a mean follow-up of 12.8 years, plasma vitamin C was inversely associated with incident cases of heart failure. Specifically, plasma vitamin C ranged from approximately 23 to 70 µmol/L in men and 33 to 82 µmol/L in women; across this range, every 20 µmol/L increase in plasma vitamin C was associated with a 9% reduction in risk of heart failure. Although a primary source of dietary vitamin C, consumption of fruit and vegetables — assessed by food frequency questionnaire — was not found to be associated with a lower risk of congestive heart failure (49). This highlights the fact that limitations associated with dietary assessment methods such as food frequency questionnaires may be overcome by using biomarkers of nutrient intake (50, 51).

A 2017 review of eight published randomized controlled trials found inconsistent results from seven trials reporting on the effect of vitamin C supplementation on serum cholesterol and triglycerides, established risk factors for cardiovascular disease (52). Only one large trial in more than 14,000 older men participating in the Physicians' Health Study II (PHS II) reported on cardiovascular outcomes. PHS II found that vitamin C supplementation (500 mg/day) for an average of eight years had no significant effect on major cardiovascular events, total myocardial infarction, or cardiovascular mortality (53). Notably, this study had several limitations (54), including no measurement of vitamin C status and the recruitment of a well-nourished study population.

There is a need for better quality studies to examine the effect of vitamin C on cardiovascular endpoints in participants with elevated risk of cardiovascular disease.

Stroke

A cerebrovascular event, or stroke, can be classified as hemorrhagic or ischemic. Hemorrhagic stroke occurs when a weakened blood vessel ruptures and bleeds into the surrounding brain tissue. Ischemic stroke occurs when an obstruction within a blood vessel blocks blood flow to the brain. Most (~80%) cerebrovascular events in high-income countries are ischemic in nature and associated with atherosclerosis as an underlying condition (55, 56).

With respect to vitamin C and cerebrovascular disease, a prospective cohort study that followed more than 2,000 residents of a rural Japanese community for 20 years found that the risk of stroke in those with the highest serum concentrations of vitamin C was 29% lower than in those with the lowest serum concentrations of vitamin C (57). Similarly, the EPIC-Norfolk study, a 10-year prospective cohort study in 20,649 adults, found that individuals with plasma vitamin C concentrations in the top quartile (25%) had a 42% lower risk of stroke compared to those in the lowest quartile (≥66 µmol/L vs. <41 µmol/L) (58). In both the Japanese (57) and EPIC-Norfolk (58) populations, blood vitamin C concentrations were highly correlated with fruit and vegetable intake. Therefore, as in many studies of vitamin C intake and chronic disease risk, it is difficult to separate the effects of vitamin C from the effects of other components of fruit and vegetables. For example, potassium — found at high levels in bananas, potatoes, and other fruit and vegetables — is known to be important in blood pressure regulation, and elevated blood pressure is a major risk factor for stroke (see the article on Potassium). A 2013 meta-analysis of 17 prospective cohort studies reported a 19% lower risk of stroke with the highest versus lowest dietary vitamin C intakes and a 38% lower risk with the highest versus lowest circulating vitamin C concentrations (59).

A randomized, double-blind, placebo-controlled trial in more than 14,000 older men participating in the Physicians' Health Study II (PHS II) found that vitamin C supplementation (500 mg/day) for an average of eight years had no significant effect on the incidence of or mortality from any type of stroke (53). Other trials also failed to show any evidence of an effect of vitamin C on the risk of stroke. A meta-analysis of 10 trials that examined antioxidant vitamins, of which five included vitamin C, found no association between any antioxidant vitamin (vitamin C, vitamin E, or β-carotene), administered alone or in combination, and risk of stroke (60).

Cancer

Overall, observational prospective cohort studies have reported no or modest inverse associations between vitamin C intake and the risk of developing a given type of cancer (37, 61-63). Additional detail is provided below for those cancer subtypes with substantial scientific information obtained from prospective cohort studies. Randomized, double-blind, placebo-controlled trials that have tested the effect of vitamin C supplementation (alone or in combination with other antioxidant nutrients) on cancer incidence or mortality have shown no effect (64).

Breast cancer

Two large prospective studies found dietary vitamin C intake to be inversely associated with breast cancer incidence in certain subgroups. In the Nurses' Health Study, premenopausal women with a family history of breast cancer who consumed an average of 205 mg/day of vitamin C from food had a 63% lower risk of breast cancer than those who consumed an average of 70 mg/day (65). In the Swedish Mammography Cohort, overweight women who consumed an average of 110 mg/day of vitamin C had a 39% lower risk of breast cancer compared to overweight women who consumed an average of 31 mg/day (66). More recent prospective cohort studies have reported no association between dietary and/or supplemental vitamin C intake and breast cancer (67-69).

Stomach cancer

A number of observational studies have found increased dietary vitamin C intake to be associated with decreased risk of gastric (stomach) cancer, and laboratory experiments indicate that vitamin C inhibits the formation of carcinogenic N-nitroso compounds in the stomach (70-72). A nested case-control study in the EPIC study found a 45% lower risk of gastric cancer incidence in individuals in the highest (≥51 µmol/L) versus lowest (<29 µmol/L) quartile of plasma vitamin C concentration; no association was observed between dietary vitamin C intake and gastric cancer (73).

Infection with the bacteria, *Helicobacter pylori* (*H. pylori*), is known to increase the risk of stomach cancer and is associated with lower vitamin C content of stomach secretions (74, 75). Although two intervention studies failed to show a reduction in stomach cancer incidence with vitamin C supplementation (35), some research suggests that vitamin C supplementation may be a useful addition to standard *H. pylori* eradication therapy in reducing the risk of gastric cancer (76). Because vitamin C can inactivate urease (an enzyme that facilitates *H. pylori* survival and colonization of the gastric mucosa at low pH) *in vitro*, vitamin C may be most effective as a prophylactic agent in those without achlorhydria (77, 78).

Colon cancer

By pooling data from 13 prospective cohort studies comprising 676,141 participants, it was determined that dietary intake of vitamin C was not associated with colon cancer, while total intake of vitamin C (i.e., from food and supplements) was associated with a 19% reduced risk of colon cancer (79). Each of the cohort studies used self-administered food frequency questionnaires at baseline to assess vitamin C intake. Although the analysis adjusted for several lifestyle and known risk factors, the authors noted that other healthy behaviors and/or folate intake may have confounded the association.

Non-Hodgkin lymphoma

A population-based, prospective study, the Iowa Women's Health Study, collected baseline data on diet and supplement use in 35,159 women (aged 55-69 years) and evaluated the risk of developing non-Hodgkin lymphoma (NHL) over 19 years of follow-up (80). Overall, an inverse association between fruit and vegetable intake and risk of NHL was observed. Additionally, dietary, but not supplemental, intake of vitamin C and other antioxidant nutrients (carotenoids, proanthocyanidins, and manganese) was inversely associated with NHL risk. Another large, multi-center, prospective study — the Women's Health Initiative — that followed 154,363 postmenopausal women for 11 years found that dietary and supplemental vitamin C intake at baseline was inversely associated with diffuse B-cell lymphoma, a subtype of NHL (81).

Other site-specific cancer types

The Physicians' Health Study II was a randomized, placebo-controlled trial that examined the effect of vitamin E (400 IU/day), vitamin C (500 mg/day), and a multivitamin supplement on the risk of cancer in 14,641 middle-aged male physicians over 10.3 years (7.6 years of active treatment plus 2.8 years post-treatment follow-up) (82). Supplementation with vitamin C had no effect on the overall risk of cancer or on the risk of prostate, bladder, or pancreatic cancer; there was a marginal reduction in colorectal cancer incidence with vitamin C compared to placebo (82).

Type 2 diabetes mellitus

In the National Institutes of Health (NIH)-American Association of Retired Persons (AARP) Diet and Health study that included 232,007 participants, the use of vitamin C supplements for at least seven times a week was associated with a 9% lower risk of developing type 2 diabetes mellitus compared to non-supplement use (83). In a cohort of 21,831 adults followed for 12 years in the EPIC-Norfolk study, high plasma vitamin C was found to be strongly associated with a reduced risk of diabetes (84). Additionally, several cross-sectional studies reported inverse associations between circulating vitamin C concentrations and markers of insulin resistance or glucose intolerance, such as glycated hemoglobin (HbA1c) concentration (50, 85, 86). Yet, short-term randomized controlled studies have found no effect of vitamin C supplementation on fasting glucose, fasting insulin, and HbA1c concentrations in healthy individuals (87). It is not known whether supplemental vitamin C could improve markers of glycemic control in subjects at risk of diabetes.

Adverse pregnancy outcomes

A 2015 meta-analysis of 29 randomized controlled trials found that administration of vitamin C during pregnancy, alone or in combination with a few other supplements, failed to reduce the risks of stillbirth, perinatal death, intrauterine growth restriction, preterm birth, premature rupture of membranes, and preeclampsia (88). Nonetheless, vitamin C supplementation led to a 36% lower risk of placental abruption and to a significant increase in gestational age at birth (88). Another meta-analysis of 40 randomized controlled trials in 276,820 women found no effect of vitamin C, alone or combined with vitamin E or multivitamins, when supplemented during pregnancy (starting prior to 20 weeks' gestation), on the risks of overall fetal loss, miscarriage, stillbirth, and congenital malformation (89).

Cigarette smoking during pregnancy causes intrauterine growth restriction and preterm birth, among other pregnancy complications (90, 91), and is the primary cause of childhood respiratory illness (92). For some still unclear reasons, smoking has been associated with a lower risk of preeclampsia during pregnancy (93). A secondary analysis of a multicenter, randomized, double-blind, placebo-controlled trial in nearly 10,000 pregnant women found no reduction in the risk of preeclampsia with supplemental vitamin C (1,000 mg/day) and vitamin E (400 IU/day), regardless of women's smoking status during pregnancy. However, antioxidant supplementation resulted in reduced risks of placental abruption and preterm birth in women who smoked during pregnancy but not in non-smokers (94). Another pilot multicenter trial found better lung function during the first week of life and lower risk of wheezing through one year of age in infants whose smoking mothers were randomized to receive vitamin C (500 mg/day) rather than a placebo during pregnancy (95). The Vitamin C to Decrease the Effects of Smoking in Pregnancy on Infant Lung Function [VCSIP] study is an ongoing trial designed to confirm these preliminary observations using more accurate measurements of pulmonary function in a larger sample of women randomized to receive supplemental vitamin C or placebo (96).

Alzheimer's disease

In the US, Alzheimer's disease (AD) is the most common form of dementia, affecting 5.5 million individuals 65 years and over (97). Oxidative stress, neuroinflammation, β-amyloid plaque deposition, Tau protein-forming tangles, and neuronal cell death in the brain of subjects affected by AD have been associated with cognitive decline and memory loss. Lower vitamin C concentrations in the cerebrospinal fluid (CSF) and brain extracellular matrix of a mouse model of AD were found to increase oxidative stress and accelerate amyloid deposition and disease progression (98). In another AD mouse model that was lacking the ability to synthesize vitamin C, supplementation with a high versus low dose of vitamin C reduced amyloid deposition in the cortex and hippocampus and limited blood-brain barrier impairments and mitochondrial dysfunction (99).

The majority of large, population-based studies examining the relationship of vitamin C intake or supplementation with AD incidence have reported null results (100). In contrast, observational studies reported lower plasma vitamin C concentrations in AD patients compared to cognitively healthy subjects (101) and found better cognitive function or lower risk of cognitive impairment with higher plasma vitamin C (100).

Few studies have measured vitamin C concentration in the CSF, which more closely reflects the vitamin C status of the brain. Vitamin C is concentrated in the brain through a combination of active transport into brain tissue and retention via the blood-brain barrier (100). Although CSF vitamin C is maintained at concentrations several-fold higher than plasma vitamin C, the precise function of vitamin C in cognitive function and AD etiology is not yet fully understood (102). In a small, longitudinal biomarker study in 32 individuals with probable AD, a higher CSF-to-plasma vitamin C ratio at baseline was associated with a slower rate of cognitive decline at one year of follow-up (103). Impaired blood-brain barrier integrity may affect the brain's ability to retain vitamin C and thus to maintain a high CSF-to-plasma vitamin C ratio. The significance of the CSF-to-plasma vitamin C ratio in AD progression requires further study.

The effect of vitamin C supplementation, in combination with other antioxidants, on CSF biomarkers and cognitive function has been examined in only a few trials involving AD patients. In a small (n=23), open-label trial, combined supplementation with vitamin C (1,000 mg/day) and vitamin E (400 IU/day) to AD patients taking a cholinesterase inhibitor significantly increased antioxidant levels and decreased lipoprotein oxidation in CSF after one year, but had no effect on the clinical course of AD compared to controls (104). A similar finding was obtained in a double-blind, randomized controlled trial in which combined supplementation with vitamin C (500 mg/day), vitamin E (800 IU/day), and α-lipoic acid (900 mg/day) for 16 weeks reduced lipoprotein oxidation in CSF but elicited no clinical benefit in individuals with mild-to-moderate AD (n=78) (105). In this latter trial, a greater decline in the Mini Mental State Examination (MMSE) score was observed in the supplemented group, however, the significance of this observation remains unclear. A third placebo-controlled trial in mildly cognitively impaired older adults (ages, 60-75 years) found that one-year supplementation with vitamin C (400 mg/day) and vitamin E (300 mg/day) improved antioxidant blood capacity but had no effect on MMSE scores (106).

At this time, avoidance of vitamin C deficiency or insufficiency, rather than supplementation in replete individuals, seems prudent for the promotion of healthy brain aging (101).

Cataracts

The lens of the eye focuses light, producing a clear, sharp image on the retina, a layer of tissue on the inside back wall of the eyeball. Age-related changes to the lens (thickening, loss of flexibility) and oxidative damage contribute to the formation of cataract, i.e., cloudiness or opacity in the lens that interferes with the clear focusing of images on the retina.

In humans, vitamin C concentration is about 15 to 20 times higher in the aqueous humor — fluid that fills the anterior and posterior chambers of the eye — than in plasma, suggesting that the vitamin may be playing an important role in the eye (107). Decreased vitamin C concentrations in the lens of the eye have been associated with increased severity of cataracts (108). A meta-analysis of observational studies found that a reduced risk of age-related cataract with higher dietary vitamin C intakes in case-control studies and with higher circulating vitamin C concentrations in cross-sectional studies. However, no such associations were found in pooled analyses of prospective cohort studies (109). In fact, two prospective cohort studies in Swedish men (110) and women (111) reported that high-dose single nutrient supplements of vitamin C were associated with an increased risk of cataract, especially in those on corticosteroid therapy.

A 2012 review of nine randomized controlled trials found no substantial effect of β-carotene, vitamin C, and vitamin E, administered individually or in combination over 2.1 to 12 years, on the risk of cataracts or cataract surgery (112). Although trials do not currently support the use of high-dose supplementation with vitamin C in cataract prevention, there is a consistent inverse association observed between high daily intake of fruit and/or vegetables (>5 servings/day) and risk of cataract (113).

Gout

Gout, a condition that afflicts more than 4% of US adults (114), is characterized by abnormally high blood concentrations of uric acid (urate) (115). Urate crystals may form in joints, resulting in inflammation and pain, as well as in the kidneys and urinary tract, resulting in kidney stones. The tendency to exhibit elevated blood uric acid concentrations and develop gout is often inherited; however, dietary and lifestyle modification may be helpful in both the prevention and treatment of gout (116). In an observational study that included 1,387 men, higher intakes of vitamin C were associated with lower serum concentrations of uric acid (117). In a cross-sectional study conducted in 4,576 African Americans, the odds of having hyperuricemia was associated with dietary intakes high in fructose, low in vitamin C, or with high fructose-to-vitamin C ratios (118). A prospective study that followed a cohort of 46,994 men for 20 years found that total daily vitamin C intake was inversely associated with incidence of gout, with higher intakes being associated with greater risk reductions (119). The results of this study also indicated that supplemental vitamin C may be helpful in the prevention of gout (119).

A 2011 meta-analysis of 13 randomized controlled trials in healthy individuals with elevated serum uric acid revealed that vitamin C supplementation (a median dose of 500 mg/day for a median duration of 30 days) modestly reduced serum uric acid concentrations by 0.35 mg/dL compared to placebo (120). Such a reduction falls within the range of assay variability and is unlikely to be clinically significant (121). An eight-week, open-label, controlled trial randomized 40 subjects with gout to receive either allopurinol (standard-of-care), vitamin C, or both treatments (122). The effect of vitamin C, alone or with allopurinol, decreasing serum uric acid was modest and much less than that of allopurinol alone. The trial did not examine the effect of vitamin C on other outcomes associated with gout (122).

Although observational studies suggested that supplemental vitamin C may be helpful to prevent incident and recurrent gout, this has not been demonstrated by intervention studies undertaken thus far. In addition, there is currently little evidence to support a role for vitamin C in the management of patients with gout (123).

Mortality

Two large prospective cohort studies assessed the relationship between dietary and supplemental vitamin C intakes and mortality. In the Vitamins and Lifestyle Study, 77,719 men and women (ages 50-76 years) were questioned at baseline on their use of dietary supplements during the previous 10 years (124). After five years of follow-up, vitamin C supplement use was associated with a small decreased risk of total mortality, although no association was found with cardiovascular disease- or cancer-specific mortality. In the second prospective cohort study, the Diet, Cancer and Health Study, 55,543 Danish adults (ages 50-64 years) were questioned at baseline about their lifestyle, diet, and supplement use during the previous 12 months (125). No association between dietary or supplemental intake of vitamin C and mortality was found after approximately 14 years of follow-up. In contrast, a 2014 meta-analysis of 10 prospective cohort studies in 17,696 women with breast cancer found a lower risk of total and breast cancer-specific mortality with higher supplemental and dietary vitamin C intakes (126). A 2012 meta-analysis of 29 trials found no effect of oral vitamin C, given alone or in combination with other antioxidants, on all-cause mortality (127).

In parallel to these dietary assessment studies, a strong inverse association between plasma vitamin C and mortality from all-causes, cardiovascular disease, and ischemic heart disease (and cancer in men only) was observed in the EPIC-Norfolk multicenter, prospective cohort study (128). After approximately four years of follow-up in 19,496 men and women (ages 45-79 years), a dose-response relationship was observed such that each 20 µmol/L increase in plasma vitamin C was associated with an estimated 20% risk reduction in all-cause mortality. Similarly, higher serum vitamin C concentrations were associated with decreased risks of cancer-specific and all-cause mortality in 16,008 adults from the US National Health and Nutrition Examination Survey (NHANES) III (1994-1998) (129).

Disease Treatment

Cardiovascular disease

Complications of cardiac procedures and surgeries

Periprocedural myocardial injury: Coronary angioplasty (also called percutaneous transluminal coronary angioplasty) is a nonsurgical procedure for treating obstructive coronary heart disease (CHD), including unstable angina pectoris, acute myocardial infarction, and multivessel CHD. Angioplasty involves temporarily inserting and inflating a tiny balloon into the clogged artery to help restore the blood flow to the heart. Periprocedural myocardial injury that occurs in up to one-third of patients undergoing otherwise uncomplicated angioplasty increases the risk of morbidity and mortality at follow-up.

One randomized, placebo-controlled trial has examined the effect of intravenous vitamin C administered to patients with stable angina undergoing elective coronary angioplasty (130). Administration of a 1-gram (g) vitamin C infusion one hour prior to the angioplasty reduced the concentrations of oxidative stress markers and improved microcirculatory perfusion compared to placebo (130). Another trial randomized 532 patients to receive a 3-g vitamin C infusion or a placebo (saline solution) within six hours prior to coronary angioplasty (131). Vitamin C treatment substantially reduced the incidence of periprocedural myocardial injury, as assessed by a reduction in the concentrations of two markers of myocardial injury, namely creatine kinase and troponin-I (131). A recent randomized controlled trial assessed the effect of vitamin C and vitamin E administration on reperfusion damage in patients who experienced acute myocardial infarction and underwent coronary angioplasty (see below) (132).

Myocardial reperfusion injury: Reperfusion injury refers to tissue damage occurring at the time of blood flow restoration (reperfusion) following transient ischemia. The heart muscle may become oxygen-deprived (ischemic) as the result of myocardial infarction or with aortic clamping during coronary artery bypass graft (CABG) surgery. Increased generation of reactive oxygen species (ROS) when the heart muscle's oxygen supply is restored might be an important contributor to myocardial damage occurring at reperfusion (133). Myocardial reperfusion injury leads to complications, such as reperfusion arrhythmias (see Atrial fibrillation) and myocardial stunning.

Vitamin C is depleted during and following cardiac surgery (134) and this might be due to the direct quenching of ROS, the regeneration of other antioxidants, and/or a massive synthesis of catecholamines (dopamine, epinephrine, norepinephrine) (135). Two randomized controlled trials conducted in the 1990s reported a reduction in reperfusion-induced oxidative stress and myocardial injury with intravenous (136) or oral (137) vitamin C administration prior to CABG surgery (reviewed in 135). A more recent randomized, double-blind, placebo-controlled trial has been designed to examine the effect of vitamin C and vitamin E administration on ischemia-reperfusion damage in 99 patients with acute myocardial infarction undergoing coronary angioplasty (132). Vitamin C infusion (sodium ascorbate: 3.20 mmol/min for 1 hour then 0.96 mmol/min for 2 hours) prior to reperfusion followed by oral supplementation with vitamin C (1 g/day) and vitamin E (400 IU/day) for 84 days effectively prevented a reduction in antioxidant capacity at reperfusion and for the next six to eight hours. The protocol also limited microvascular dysfunction (i.e., improved microcirculatory perfusion) and improved left ventricular ejection fraction at discharge (on day 84) (138, 139). However, no difference in the infarct size between antioxidant vitamin treatment and placebo was seen (138).

Atrial fibrillation: Atrial fibrillation is the most common type of cardiac arrhythmia. It is also a common post-cardiac surgery complication, leading to an increased risk of cardiovascular morbidity (e.g., heart failure, stroke) and mortality. Three meta-analyses of prospective cohort studies and randomized controlled trials have reported an overall reduction in the risk of post-operative atrial fibrillation following administration of primarily oral vitamin C (140-142). In most trials, participants received 2 g of vitamin C prior to undergoing CABG or valve replacement surgery and 1 to 2 g/day for five days post-surgery. Although only a minority of trials delivered vitamin C intravenously, this administration route appeared to be more effective at reducing the risk of atrial fibrillation — presumably due to higher plasma concentrations achieved (140). Of note, a subgroup analysis in one of the meta-analyses showed a reduction of post-operative atrial fibrillation with vitamin C in non US-based trials (10 trials) but no effect of vitamin C in US-based trials (5 trials) (140).

Cerebral ischemia-reperfusion injury

A small randomized controlled trial performed in 60 ischemic stroke patients showed that intravenous vitamin C administration (500 mg/day for 10 days, initiated day 1 post-stroke) had no effect on serum markers of oxidative stress or neurological outcomes compared to placebo (143).

Vascular complications of diabetes mellitus

Cardiovascular disease (CVD) is the leading cause of death in individuals with diabetes mellitus. The role of increased oxidative stress in the occurrence of vascular complications in subjects with diabetes has led to hypothesis that higher intakes of antioxidant nutrients could help lower the risk of CVD in diabetic subjects (144). A 2018 meta-analysis of randomized controlled trials investigating the effect of antioxidant vitamin supplementation in patients with type 2 diabetes found that most improvement in markers of oxidative stress and blood glucose control could be attributed to vitamin E (145). Another meta-analysis of trials found no effect of vitamins E and C, alone or in combination, on measures of β-cell function and insulin resistance (146). Yet, most studies were small and of short duration and thus did not assess the consequence of long-term use of antioxidant vitamins on the risk of vascular complications in diabetic patients. One 12-month randomized placebo-controlled trial in 456 participants with type 2 diabetes treated with metformin examined the effect of vitamin C (500 mg/day) or acetylsalicylic acid (aspirin; 100 mg/day) on risk factors for diabetes-related complications such as CVD (147). Both vitamin C and aspirin reduced fasting blood glucose and HbA1c concentrations and improved blood lipid profile in metformin-treated patients. Compared to placebo, both treatments were found to be more likely to limit risk factors contributing to diabetes-related complications, as well as to lower the risk of future cardiovascular events over a 10-year period (estimated using the Framingham risk score) (147).

Of note, it is possible that genetic differences among diabetic patients influence the effect of vitamin C supplementation on cardiovascular risk. In particular, a specific allele of the haptoglobin gene (Hp), namely Hp2, appears to be associated with an increased risk of diabetic vascular complications. Carriers of two copies of the Hp2 allele (Hp2-2) express a Hp protein that has a lower capacity to bind and remove pro-oxidant, free hemoglobin (Hb) from plasma, compared to Hp proteins coded by the Hp1-1 and Hp1-2 genotypes. When the results of the Women's Antioxidant Vitamin Estrogen (WAVE) trial were reanalyzed based on Hp genotype, antioxidant therapy (1,000 mg/day of vitamin C + 800 IU/day of vitamin E) was associated with improvement of coronary atherosclerosis in diabetic women with Hp1-1 genotype but worsening of coronary atherosclerosis in those carrying the Hp2-2 genotype (148). Results from another study by the same investigators suggested that vitamin C could not prevent the oxidation of high-density lipoprotein (HDL)-cholesterol by glycated Hb-Hp2-2 complexes *in vitro* nor restore impaired HDL function in diabetic mice carrying the Hp2-2 genotype (149).

Sepsis

Sepsis and septic shock — defined as persistent sepsis-induced low blood pressure — are associated with elevated mortality rates in critically ill patients (150, 151). Because systemic inflammatory responses involve excessive oxidative stress, it has been suggested that providing antioxidant nutrients like vitamin C may improve the outcome of critically ill patients in intensive care units. In addition, hypovitaminosis C is common in critically ill patients, especially in those with septic shock, and persists despite enteral/parenteral nutritional therapy providing recommended amounts of vitamin C (152). Vitamin C requirements are likely to be increased in this population due to the hypermetabolic response driven by the systemic inflammatory reaction (152, 153). Intravenous administration of 50 mg or 200 mg of vitamin C per kg per day for 96 hours to patients with sepsis admitted in intensive care unit was found to correct vitamin C deficiency. Vitamin C also prevented the rise of Sequential Organ Failure Assessment (SOFA) and Acute Physiologic Assessment and Chronic Health Evaluation (APACHE) II scores — used to assess severity of illness and risk of mortality — observed in placebo-treated patients (154). Vitamin C infusion also lowered the concentration of markers of inflammation and endothelial injury in patients compared to placebo (154). In another randomized, double-blind, controlled trial in 28 critically ill patients with septic shock, infusion of 25 mg of vitamin C per kg every six hours for 72 hours significantly limited the requirement to vasopressor norepinephrine — decreasing both the dose and duration of treatment — and dramatically improved the 28-day survival rate (155). Similar results have been reported in septic patients given intravenous vitamin C (1.5 g/6 h), hydrocortisone (50 mg/6 h), and thiamin (200 mg/12 h) until hospital discharge. Compared to standard-of-care, this intervention cocktail more than halved the mean duration of vasopressor use (18.3 h versus 54.9 h) and reduced the odds of mortality by nearly 90% (156). Although intravenous vitamin C administration appears to be safe and well tolerated, there is a non-negligible risk of oxalate nephropathy (a rare cause of kidney failure) in these critically ill patients (157).

Cancer

Route of administration

Studies in the 1970s and 1980s conducted by Linus Pauling, Ewan Cameron, and colleagues suggested that large doses of vitamin C (10 g/day infused intravenously for 10 days followed by at least 10 g/day orally indefinitely) were helpful in increasing the survival time and improving the quality of life of terminal cancer patients (158). Controversy surrounding the efficacy of least 10 g/day orally indefinitely) were helpful in increasing the survival time and improving the quality of life of terminal cancer patients (158). Controversy surrounding the efficacy of vitamin C in cancer treatment ensued, leading to the recognition that the route of vitamin C administration is critical (22, 159). Compared to orally administered vitamin C, intravenous vitamin C can result in 30 to 70-fold higher plasma vitamin C concentrations (25). Higher plasma concentrations achieved via intravenous vitamin C administration are comparable to those that are toxic to cancer cells in culture. The anticancer mechanism of intravenous vitamin C action is under investigation. It may involve the production of high levels of hydrogen peroxide, selectively toxic to cancer cells (22, 160-162), or the deactivation of hypoxia inducible factor, a prosurvival transcription factor that protects cancer cells from various forms of stress (159, 163, 164). Vitamin C likely also plays a role in the maintenance of genome integrity and in the protection against cellular transformation through regulating DNA and histone demethylating enzymes (see Function) (165).

Safety

Current evidence from controlled clinical trials indicates that intravenous vitamin C is generally safe and well tolerated in cancer patients. Of note, because intravenous administration of 80 g of vitamin C precipitated hemolytic anemia in two subjects with glucose-6-phosphate dehydrogenase deficiency, patients due to receive high-dose vitamin C infusion are systematically screened for this genetic disorder (166). Four phase I clinical trials in patients with advanced cancer found that intravenous administration of vitamin C at doses up to 1.5 g/kg of body weight (equivalent to about 100 g/day for an average weight [70 kg] person) and 70 to 80 g/m^2 was well tolerated and safe in pre-screened patients (167-170). A few observational studies in cancer patients undergoing chemotherapy and/or radiotherapy reported that complementary intravenous vitamin C treatment was associated with a reduction in treatment-associated side effects and an improved quality of life (171). A phase I study in nine patients with metastatic pancreatic cancer showed that millimolar concentrations of plasma vitamin C could be reached safely when administered in conjunction with the cancer chemotherapy drugs, gemcitabine and erlotinib (168).

Sensitivity to vitamin C

Retrospective *in vitro* colony formation assays revealed that patient leukemic cells displayed variable sensitivity to vitamin C treatment: leukemic cells from seven out of the nine patients who experienced a significant clinical benefit were sensitive to vitamin C *in vitro* (i.e., "responders"); the leukemic cells from the remaining six patients were not sensitive to vitamin C (i.e., "non-responders"). Thus, *in vitro* vitamin C sensitivity assays may provide predictive value for the clinical response to intravenous vitamin C treatment. The mechanisms underlying differential sensitivity to vitamin C are under investigation. *In vitro* experiments performed using 11 different cancer cell lines demonstrated that sensitivity to vitamin C correlated with the expression of catalase, an enzyme involved in the decomposition of hydrogen peroxide (172). Approximately one-half of the cell lines tested were resistant to vitamin C cytotoxicity, a response associated with high levels of catalase activity.

Sensitivity to vitamin C may also be determined by the expression of sodium-dependent vitamin C transporter-2 (SVCT-2), which transports vitamin C into cells (173). Higher SVCT-2 levels were associated with enhanced sensitivity to vitamin C in nine different breast cancer cell lines. Moreover, SVCT-2 was significantly expressed in 20 breast cancer tissue samples, but weakly expressed in normal tissues. Finally, mutations in genes coding for vitamin C-dependent TET demethylases, mutations that are common in cancer cells, may also contribute to resistance to vitamin C treatment (165).

Efficacy

Current evidence of the efficacy of intravenous vitamin C in cancer patients is limited to observational studies, uncontrolled interventions, and case reports (174, 175). There is a need for larger, longer-duration phase II clinical trials that test the efficacy of intravenous vitamin C in disease progression and overall survival (176).

Common cold

The work of Linus Pauling stimulated public interest in the use of doses greater than 1 g/day of vitamin C to prevent the common cold (177). In the past 40 years, numerous placebo-controlled trials have examined the effect of vitamin C supplementation on the prevention and treatment of colds. A 2013 meta-analysis of 53 placebo-controlled trials evaluated the effect of vitamin C supplementation on the incidence, duration, or severity of the common cold when taken as a continuous daily supplement (43 trials) or as therapy upon onset of cold symptoms (10 trials) (178). Regarding the incidence of colds, a difference was observed between two groups of participants. Regular supplementation with vitamin C (0.25 to 2 g/day) did not reduce the incidence of colds in the general population (23 trials); however, in participants undergoing heavy physical stress (e.g., marathon runners, skiers, or soldiers in subarctic conditions), vitamin C supplementation halved the incidence of colds (5 trials). A benefit of regular vitamin C supplementation was also seen in the duration of colds, with a greater benefit in children than in adults: The pooled effect of vitamin C supplementation was a 14% reduction in cold duration in children and an 8% reduction in adults. Finally, no significant effect of vitamin C supplementation (1-8 g/day) was observed in therapeutic trials in which vitamin C was administered after cold symptoms occurred.

In addition, a 2013 systematic review by the same investigators identified only two small randomized, double-blind, placebo-controlled trials that examined the effect of vitamin C on the incidence of respiratory infection-induced asthma (179). One trial found that vitamin C supplementation (1 g/day) for 14 weeks reduced the risk of asthma attacks precipitated by respiratory infection. The other trial randomized subjects diagnosed with infection-related asthma to receive 5 g/day of vitamin C or a placebo for one week; a lower proportion of participants was found to present with bronchial hypersensitivity to histamine — which characterizes chronic asthma — in the vitamin C group compared to the control group (reviewed in 179). These observations need to be confirmed in larger, well-designed trials.

Asthma

A 2013 systematic review identified 11 randomized controlled studies that evaluated the effect of vitamin C on asthma (eight trials) or exercise-induced bronchoconstriction (three trials) (180). Exercise-induced bronchoconstriction is a transient narrowing of the airways that occurs after exercise and is indicated by a ≥10% decline in Forced Expiratory Volume in 1 second (FEV_1). In the three trials that included a total of 40 participants with exercise-induced bronchoconstriction, vitamin C administration before exercise (a 0.5-g dose on two subsequent days in one trial, a single dose of 2 g in the second trial, and 1.5 g daily for two weeks in the third trial) significantly reduced the exercise-induced decline in FEV_1. Among the five out of eight trials in asthmatic subjects that reported on FEV_1 outcomes, none found a difference between vitamin C supplementation and placebo (180).

Lead toxicity

Although the use of lead paint and leaded gasoline has been discontinued in the US, lead toxicity continues to be a significant health problem, especially in children living in urban areas. Abnormal growth and development have been observed in infants of women exposed to lead during pregnancy, while children who are chronically exposed to lead are more likely to develop learning disabilities, behavioral problems, and to have a low IQ. In adults, lead toxicity may result in kidney damage, high blood pressure, and anemia.

Several cross-sectional studies have reported an inverse association between vitamin C status and blood lead concentration. For instance, in a study of 747 older men, blood lead concentration was significantly higher in those who reported total dietary vitamin C intakes averaging less than 109 mg/day compared to those with higher vitamin C intakes (181). A much larger study of 19,578 people, including 4,214 children from 6 to 16 years of age, found higher serum vitamin C concentrations to be associated with significantly lower blood lead concentrations (182). A US national survey of more than 10,000 adults found that blood lead concentrations were inversely related to serum vitamin C concentrations (183).

Cigarette smoking or second-hand exposure to cigarette smoke contributes to increased blood lead concentration and a state of chronic low-level lead exposure. An intervention trial in 75 adult male smokers found that supplementation with 1,000 mg/day of vitamin C resulted in significantly lower blood lead concentration over a four-week treatment period compared to placebo (184). A lower dose of 200 mg/day did not significantly affect blood lead concentration, although serum vitamin C concentrations were not different from those in the group who took 1,000 mg/day.

The mechanism(s) by which vitamin C reduces blood lead concentration is not known, yet it has been proposed that vitamin C could inhibit intestinal absorption (184) or enhance urinary excretion of lead (185).

Sources

Unlike plants and most animals, humans have lost the ability to synthesize vitamin C endogenously and therefore have an essential dietary requirement for this vitamin (see The Recommended Dietary Allowance). Results from 7,277 participants in the US National Health and Nutrition Examination Survey (NHANES) 2003-2004 indicated that an estimated 7.1% of individuals ages ≥6 years were deficient in vitamin C — based on serum vitamin C concentrations <11.4 µmol/L (36). The national study identified smokers and those of lower socioeconomic status to both be at higher risk for vitamin C deficiency (36).

Food sources

As shown in **Table 3**, different fruit and vegetables vary in their vitamin C content, but five servings (2½ cup-equivalents) of a variety of fruit and vegetables should average out to about 150 to 200 mg of vitamin C, especially if vitamin C-rich fruits are consumed. If you wish to check foods for their vitamin C content, search USDA's FoodData Central.

Table 3. Some Food Sources of Vitamin C

Food	Serving	Vitamin C (mg)
Kiwifruit, Zespri SunGold	1 fruit (81 g)	131
Grapefruit juice, pink, raw	¾ cup (6 ounces)	94
Orange juice, raw	¾ cup (6 ounces)	93
Strawberries	1 cup, whole	85
Grapefruit juice, white, raw	¾ cup (6 ounces)	70
Kiwifruit	1 fruit (74 g)	69
Orange	1 medium	65
Sweet red pepper, raw	½ cup, chopped	59
Broccoli, cooked	½ cup	51
Grapefruit, raw	½ medium	44
Brussel sprouts, cooked	½ cup	37
Potato, white, flesh and skin	1 medium, baked	22
Tomato, red, ripe, raw	1 medium	17
Banana, raw	1 medium	10
Apple, raw	1 medium	8
Spinach, raw	1 cup	8

Supplements

Vitamin C (L-ascorbic acid) is available in many forms, but there is little scientific evidence that any one form is better absorbed or more effective than another. Most experimental and clinical research uses ascorbic acid or its sodium salt, called sodium ascorbate. Natural and synthetic L-ascorbic acid are chemically identical and there are no known differences regarding biological activities or bioavailability (186).

Mineral ascorbates

Mineral salts of vitamin C are considered less acidic than vitamin C and therefore are considered "buffered." Some people find them less irritating to the gastrointestinal tract than ascorbic acid. Sodium ascorbate and calcium ascorbate are the most common forms, although a number of other mineral ascorbates are available. Sodium ascorbate provides 111 mg of sodium (889 mg of ascorbic acid) per 1,000 mg of sodium ascorbate, and calcium ascorbate generally provides 90 to 110 mg of calcium (890-910 mg of ascorbic acid) per 1,000 mg of calcium ascorbate.

Vitamin C with flavonoids

Flavonoids are a class of water-soluble plant pigments that are often found in vitamin C-rich fruit and vegetables, especially citrus fruit and berries (see the article on Flavonoids). There is little evidence that the flavonoids in most commercial preparations increase the bioavailability or efficacy of vitamin C (187). Some, yet not all, studies in animal models such as vitamin C-deficient guinea pigs or genetically scorbutic rats found an increased uptake of vitamin C in peripheral circulation and specific organs in the presence of flavonoids. However, studies conducted in humans found no differences in bioavailability of vitamin C from flavonoid-rich whole fruit or fruit juice and synthetic vitamin C (reviewed in 186).

Vitamin C and metabolites

One supplement, Ester-C®, contains mainly calcium ascorbate and includes small amounts of the vitamin C metabolites, dehydroascorbic acid (oxidized ascorbic acid), calcium threonate, and trace amounts of xylonate and lyxonate. Although these metabolites are purported to increase the bioavailability of vitamin C, the only published study in humans addressing this issue found no difference between Ester-C® and commercially available vitamin C tablets with respect to the absorption and urinary excretion of vitamin C (187). Ester-C® should not be confused with ascorbyl palmitate, which is also marketed as "vitamin C ester" (see below).

Ascorbyl palmitate

Ascorbyl palmitate is a vitamin C ester (i.e., ascorbic acid linked to a fatty acid). In this case, vitamin C is esterified to the saturated fatty acid, palmitic acid, resulting in a fat-soluble form of vitamin C. Ascorbyl palmitate has been added to a number of skin creams due to interest in its antioxidant properties, as well as its importance in collagen synthesis (see the separate article, Vitamin C and Skin Health) (188). Although ascorbyl palmitate is also available as an oral supplement, most of it is likely hydrolyzed to ascorbic acid and palmitic acid in the digestive tract before it is absorbed (189). Ascorbyl palmitate is marketed as "vitamin C ester," which should not be confused with Ester-C® (see above).

Other formulations of vitamin C

One small placebo-controlled, cross-over trial in 11 men showed that the oral administration of 4 g of vitamin C resulted in a greater vitamin C concentration in plasma over a four-hour period when vitamin C was encapsulated in liposomes compared to unencapsulated vitamin C (190). Although liposomal encapsulation could increase vitamin C bioavailability, plasma vitamin C concentrations were much lower than those achieved with intravenous vitamin C administration (190).

For a more detailed review of scientific research on the bioavailability of different forms of vitamin C, see The Bioavailability of Different Forms of Vitamin C.

Safety

Toxicity

A number of possible adverse health effects of very large doses of vitamin C have been identified, mainly based on *in vitro* experiments or isolated case reports, and include genetic mutations, birth defects, cancer, atherosclerosis, kidney stones, "rebound scurvy," increased oxidative stress, excess iron absorption, vitamin B_{12} deficiency, and erosion of dental enamel. However, none of these alleged adverse health effects have been confirmed in subsequent studies, and there is no reliable scientific evidence that doses of vitamin C up to 10 g/day in adults are toxic or detrimental to health. The concern of kidney stone formation with vitamin C supplementation is discussed below.

With the latest RDA published in 2000, a tolerable upper intake level (UL) for vitamin C was set for the first time (**Table 4**). A UL of 2 g (2,000 mg) daily was recommended in order to prevent generally healthy adults from experiencing diarrhea and gastrointestinal disturbances (35). Such symptoms are not generally serious, especially if they resolve with temporary discontinuation of vitamin C supplementation.

Table 4. Tolerable Upper Intake Level (UL) for Vitamin C

Age Group	UL (mg/day)
Infants 0-12 months	Not possible to establish*
Children 1-3 years	400
Children 4-8 years	650
Children 9-13 years	1,200
Adolescents 14-18 years	1,800
Adults 19 years and older	2,000
*Source of intake should be from foods or formula only.	

Kidney stones

Because oxalate is a metabolite of vitamin C, there is some concern that high vitamin C intake could increase the risk of calcium oxalate kidney stones. Some (24, 191, 192), but not all (193-195), studies have reported that supplemental vitamin C increases urinary oxalate concentrations. Whether any increase in oxalate levels would translate to an elevation in risk for kidney stones has been examined in several epidemiological studies. Two large prospective cohort studies, one following 45,251 men for six years and the other following 85,557 women for 14 years, reported that consumption of ≥1,500 mg of vitamin C daily did not increase the risk of kidney stone formation compared to those consuming <250 mg daily (196, 197). On the other hand, two other large prospective studies reported that a high intake of vitamin C was associated with an increased risk of kidney stone formation in men (198, 199). Specifically, the Health Professionals Follow-Up Study collected data on dietary and supplemental vitamin C intake every four years in 45,619 male health professionals (ages 40-75 years) (198). After 14 years of follow-up, it was found that men who consumed ≥1,000 mg/day of vitamin C had a 41% higher risk of kidney stones compared to men consuming <90 mg of vitamin C daily. In the Cohort of Swedish Men study, self-reported use of single-nutrient vitamin C supplements (taken seven or more times per week) at baseline was associated with a two-fold higher risk of incident kidney stones among 48,840 men (ages 45-79 years) followed for 11 years (199). Despite conflicting results, it may be prudent for individuals predisposed to oxalate kidney stone formation to avoid high-dose vitamin C supplementation.

Drug interactions

Overall, evidence suggesting specific drugs can lower blood vitamin C concentrations in humans is limited. Dihydropyridine calcium channel blockers (e.g., nicardipine, nifedipine) can inhibit vitamin C uptake by intestinal cells *in vitro*. However, a reduction in blood vitamin C concentrations with these drugs has not been reported in humans (200). Aspirin can impair vitamin C status if taken frequently (201).

Conversely, there are case reports suggesting that supplemental vitamin C may lower blood concentrations of some medications, such as fluphenazine (the antipsychotic drug, Prolixin) and indinavir (the antiretroviral drug, Crixivan) (200). There is some evidence, though controversial, that vitamin C interacts with anticoagulant medications like warfarin (Coumadin). Large doses of vitamin C may block the action of warfarin and thus lower its effectiveness. Individuals on anticoagulants should limit their vitamin C intake to <1 g/day and have their prothrombin time monitored by the clinician following their anticoagulant therapy (200). In addition, vitamin C may bind aluminum in the gut and increase the absorption of aluminum-containing compounds (e.g., aluminum-containing antacids, aluminum-containing phosphate binders). People with impaired kidney function may be at risk for aluminum toxicity when supplemental vitamin C is taken at the same time as these compounds (200, 201). Finally, supplemental vitamin C may increase blood estrogen concentrations in women using oral contraceptives or hormone replacement therapy (200).

The potential effect of antioxidants during chemotherapy is not well understood, yet only likely to be an issue if a specific chemotherapeutic agent acts through an oxidative mechanism, which is uncommon (171). It is not clear whether vitamin C given parenterally could diminish or increase the efficacy of chemotherapy drugs — in particular, akylating agents (e.g., cyclophosphamide, busulfan), antitumor antibiotics (e.g., doxorubicin, bleomycin), and arsenic trioxide. Patients are advised to discuss with their oncologist before using vitamin C supplements (200, 201).

Because high doses of vitamin C have also been found to interfere with the interpretation of certain laboratory tests (e.g., serum bilirubin, serum creatinine, and the stool guaiac assay for occult blood), it is important to inform one's health care provider of any recent supplement use.

Antioxidant supplements and HMG-CoA reductase inhibitors (statins)

A three-year randomized controlled trial in 160 patients with documented coronary heart disease and low blood HDL concentrations found that a combination of simvastatin (Zocor) and niacin increased HDL concentration, inhibited the progression of coronary artery stenosis (narrowing), and decreased the frequency of cardiovascular events, such as myocardial infarction and stroke (202). Surprisingly, when an antioxidant combination (1,000 mg vitamin C, 800 IU vitamin E, 100 μg selenium, and 25 mg β-carotene daily) was taken with the simvastatin-niacin combination, the protective effects were diminished. Since the antioxidants were taken together in this trial, the individual contribution of vitamin C cannot be determined. In contrast, a much larger trial in more than 20,000 men and women with coronary heart disease or diabetes mellitus found that simvastatin and an antioxidant combination (600 mg vitamin E, 250 mg vitamin C, and 20 mg β-carotene daily) did not diminish the cardioprotective effects of simvastatin therapy over a five-year period (203). These contradictory findings indicate that further research is needed on potential interactions between antioxidant supplements and cholesterol-lowering drugs, such as HMG-CoA reductase inhibitors (statins).

Does vitamin C promote oxidative damage under physiological conditions?

Vitamin C is known to function as a highly effective antioxidant in living organisms. However, in test tube experiments, vitamin C can interact with some free metal ions and lead to the generation of potentially damaging free radicals. Although free metal ions are not generally found under physiological conditions, the idea that high doses of vitamin C might be able to promote oxidative damage *in vivo* has received a great deal of attention. Widespread publicity has been given to a few studies suggesting a pro-oxidant effect of vitamin C (204, 205), but these studies turned out to be either flawed or of no physiological relevance. A comprehensive review of the literature found no credible scientific evidence that supplemental vitamin C promotes oxidative damage under physiological conditions or in humans (206).

Linus Pauling Institute Recommendation

Combined evidence from metabolic, pharmacokinetic, and observational studies, and from randomized controlled trials supports consuming sufficient vitamin C to achieve plasma concentrations of at least 60 µmol/L. While most generally healthy young adults can achieve these plasma concentrations with daily vitamin C intake of at least 200 mg/day, some individuals may have a lower vitamin C absorptive capacity than what is currently documented. Thus, the Linus Pauling Institute recommends a vitamin C intake of 400 mg daily for adults to ensure replete tissue concentrations (29) — an amount substantially higher than the RDA yet with minimal risk of side effects.

This recommendation can be met through food if the diet includes at least several servings of vitamin C-rich fruit and vegetables (e.g., citrus fruit, kiwifruit, peppers; see Food sources) as part of the daily recommended fruit and vegetable intake (see article on Fruit and Vegetables). Most multivitamin supplements provide at least 60 mg of vitamin C.

Older adults (>50 years)

Whether older adults have higher requirements for vitamin C is not yet known with certainty, yet some older populations have been found to have vitamin C intakes considerably below the RDA of 75 and 90 mg/day for women and men, respectively (207). A vitamin C intake of at least 400 mg daily may be particularly important for older adults who are at higher risk for age-related chronic diseases. Pharmacokinetic studies in older adults have not yet been conducted, but there is some evidence suggesting that the efficiency of one of the molecular mechanisms for the cellular uptake of vitamin C declines with age (208). Because maximizing blood concentrations of vitamin C may be important in protecting against oxidative damage to cells and biological molecules, a vitamin C intake of at least 400 mg daily might benefit older adults who are at higher risk for chronic diseases caused, in part, by oxidative damage, such as heart disease, stroke, certain cancers, and cataract.

For more information on the difference between Dr Linus Pauling's recommendation and the Linus Pauling Institute's recommendation for vitamin C intake, select the highlighted text.

Supplemental Forms

Español

The Bioavailability of Different Forms of Vitamin C (Ascorbic Acid)

In the rapidly expanding market of dietary supplements, it is possible to find vitamin C in many different forms with many claims regarding its efficacy or bioavailability. Bioavailability refers to the degree to which a nutrient (or drug) becomes available to the target tissue after it has been administered. We reviewed the literature for the results of scientific research on the bioavailability of different forms of vitamin C.

Natural vs. synthetic ascorbic acid

Natural and synthetic L-ascorbic acid are chemically identical, and there are no known differences in their biological activity. The possibility that the bioavailability of L-ascorbic acid from natural sources might differ from that of synthetic ascorbic acid was investigated in at least two human studies, and no clinically significant differences were observed. A study of 12 males (6 smokers and 6 nonsmokers) found the bioavailability of synthetic ascorbic acid (powder administered in water) to be slightly superior to that of orange juice, based on blood levels of ascorbic acid, and not different based on ascorbic acid in leukocytes (white blood cells) (1). A study in 68 male nonsmokers found that ascorbic acid consumed in cooked broccoli, orange juice, orange slices, and as synthetic ascorbic acid tablets are equally bioavailable, as measured by plasma ascorbic acid levels (2, 3).

Different forms of ascorbic acid

The gastrointestinal absorption of ascorbic acid occurs through an active transport process, as well as through passive diffusion. At low gastrointestinal concentrations of ascorbic acid active transport predominates, while at high gastrointestinal concentrations active transport becomes saturated, leaving only passive diffusion. In theory, slowing down the rate of stomach emptying (e.g., by taking ascorbic acid with food or taking a slow-release form of ascorbic acid) should increase its absorption. While the bioavailability of ascorbic acid appears equivalent whether it is in the form of powder, chewable tablets, or non-chewable tablets, the bioavailability of ascorbic acid from slow-release preparations is less certain.

A study of three men and one woman found 1 gram of ascorbic acid to be equally well absorbed from solution, tablets, and chewable tablets, but the absorption from a timed-release capsule was 50% lower. Absorption was assessed by measuring urinary excretion of ascorbic acid after an intravenous dose of ascorbic acid and then comparing it to urinary excretion after the oral dosage forms (4).

A more recent study examined the plasma levels of ascorbic acid in 59 male smokers supplemented for two months with either 500 mg/day of slow-release ascorbic acid, 500 mg/day of plain ascorbic acid, or a placebo. After two months of supplementation no significant differences in plasma ascorbic acid levels between the slow-release and plain ascorbic acid groups were found (5). A second placebo-controlled trial also evaluated plain ascorbic acid versus slow-release ascorbic acid in 48 male smokers (6). Participants were supplemented with either 250 mg plain ascorbic acid, 250 mg slow-release ascorbic acid, or placebo twice daily for four weeks. No differences were observed in the change in plasma ascorbate concentration or area under the curve following ingestion of either formulation.

Mineral ascorbates

Mineral salts of ascorbic acid (mineral ascorbates) are less acidic, and therefore, considered "buffered." Thus, mineral ascorbates are often recommended to people who experience gastrointestinal problems (upset stomach or diarrhea) with plain ascorbic acid. There appears to be little scientific research to support or refute the claim that mineral ascorbates are less irritating to the gastrointestinal tract. When mineral salts of ascorbic acid are taken, both the ascorbic acid and the mineral appear to be well absorbed, so it is important to consider the dose of the mineral accompanying the ascorbic acid when taking large doses of mineral ascorbates. For the following discussion, it should be noted that 1 gram (g)= 1,000 milligrams (mg) and 1 milligram (mg) = 1,000 micrograms (µg). Mineral ascorbates are available in the following forms:

- **Sodium ascorbate:** 1,000 mg of sodium ascorbate generally contains 111 mg of sodium. Individuals following low-sodium diets (e.g., for high blood pressure) are generally advised to keep their total dietary sodium intake to less than 2,500 mg/day. Thus, megadoses of vitamin C in the form of sodium ascorbate could significantly increase sodium intake (see Sodium Chloride).
- **Calcium ascorbate:** Calcium ascorbate generally provides 90-110 mg of calcium (890-910 mg of ascorbic acid) per 1,000 mg of calcium ascorbate. Calcium in this form appears to be reasonably well absorbed. The recommended dietary calcium intake for adults is 1,000 to 1,200 mg/day. Total calcium intake should not exceed the UL, which is 2,500 mg/day for adults aged 19-50 years and 2,000 mg/day for adults older than 50 years (see Calcium).

The following mineral ascorbates are more likely to be found in combination with other mineral ascorbates, as well as other minerals. It's a good idea to check the labels of dietary supplements for the ascorbic acid dose as well as the dose of each mineral. Recommended dietary intakes and maximum upper levels of intake (when available) are listed after the individual mineral ascorbates below:

- **Potassium ascorbate:** The minimal requirement for potassium is thought to be between 1.6 and 2.0 g/day. Fruit and vegetables are rich sources of potassium, and a diet rich in fruit and vegetables may provide as much as 8 to 11 g/day. Acute and potentially fatal potassium toxicity (hyperkalemia) is thought to occur at a daily intake of about 18 g/day of potassium in adults. Individuals taking potassium-sparing diuretics and those with renal insufficiency (kidney failure) should avoid significant intake of potassium ascorbate. The purest form of commercially available potassium ascorbate contains 0.175 grams (175 mg) of potassium per gram of ascorbate (see Potassium).
- **Magnesium ascorbate:** The recommended dietary allowance (RDA) for magnesium is 400-420 mg/day for adult men and 310-320 mg/day for adult women. The upper level (UL) of intake for magnesium from supplements should not exceed 350 mg/day (see Magnesium).
- **Zinc ascorbate:** The RDA for zinc is 11 mg/day for adult men and 8 mg/day for adult women. The upper level (UL) of zinc intake for adults should not exceed 40 mg/day (see Zinc).
- **Molybdenum ascorbate:** The RDA for molybdenum is 45 micrograms (µg)/day for adult men and women. The upper level (UL) of molybdenum intake for adults should not exceed 2,000 µg (2 mg)/day (see Molybdenum).
- **Chromium ascorbate:** The recommended dietary intake (AI) for chromium is 30-35 µg/day for adult men and 20-25 µg/day for adult women. A maximum upper level (UL) of intake has not been determined by the US Food and Nutrition Board (see Chromium).
- **Manganese ascorbate:** The recommended dietary intake (AI) for manganese is 2.3 mg/day for adult men and 1.8 mg/day for adult women. The upper level (UL) of intake for manganese for adults should not exceed 11 mg/day. Manganese ascorbate is found in some preparations of glucosamine and chondroitin sulfate, and following the recommended dose on the label of such supplements could result in a daily intake exceeding the upper level for manganese (see Manganese).

Vitamin C with bioflavonoids

Bioflavonoids or flavonoids are polyphenolic compounds found in plants. Vitamin C-rich fruit and vegetables, especially citrus fruit, are often rich sources of flavonoids as well. The effect of bioflavonoids on the bioavailability of ascorbic acid has been recently reviewed (7).

Results from the 10 clinical studies comparing the absorption of vitamin C alone or vitamin C in flavonoid-containing foods showed no appreciable differences in bioavailability of ascorbic acid. Only one study, which included five men and three women, found that a 500-mg supplement of synthetic ascorbic acid, given in a natural citrus extract containing bioflavonoids, proteins, and carbohydrates, was more slowly absorbed and 35% more bioavailable than synthetic ascorbic acid alone, when based on plasma levels of ascorbic acid (8). The remaining studies showed either no change or slightly lower plasma ascorbate levels in subjects who consumed vitamin C with flavonoids compared to flavonoids alone (7).

Another assessment of vitamin C bioavailability is measuring urinary ascorbate levels to approximate rates of vitamin C excretion. One study in six young Japanese males (22-26 years old) showed a significant reduction in urinary excretion of ascorbic acid in the presence of acerola juice, a natural source of both vitamin C and flavonoids (9). However, three separate studies showed that urinary levels of vitamin C were increased after consumption of kiwifruit (10), blackcurrant juice (11), or orange juice (1). Overall, the impact of flavonoids on the bioavailability of vitamin C seems to be negligible; however, there is a need for carefully controlled studies using specific flavonoid extracts (7).

Ascorbate and vitamin C metabolites (Ester-C®)

Ester-C® contains mainly calcium ascorbate, but also contains small amounts of the vitamin C metabolites, dehydroascorbic acid (oxidized ascorbic acid), calcium threonate, and trace levels of xylonate and lyxonate. In their literature, the manufacturers state that the metabolites, especially threonate, increase the bioavailability of the vitamin C in this product, and they indicate that they have performed a study in humans that demonstrates the increased bioavailability of vitamin C in Ester-C®. This study has not been published in a peer-reviewed journal. A small published study of vitamin C bioavailability in eight women and one man found no difference between Ester-C® and commercially available ascorbic acid tablets with respect to the absorption and urinary excretion of vitamin C (12). Ester-C® should not be confused with ascorbyl palmitate, which is also marketed as "vitamin C ester" (see below).

Ascorbyl palmitate

Ascorbyl palmitate is a fat-soluble antioxidant used to increase the shelf life of vegetable oils and potato chips (13). It is an amphipathic molecule, meaning one end is water-soluble and the other end is fat-soluble. This dual solubility allows it to be incorporated into cell membranes. When incorporated into the cell membranes of human red blood cells, ascorbyl palmitate has been found to protect them from oxidative damage and to protect α-tocopherol (a fat-soluble antioxidant) from oxidation by free radicals (14). However, the protective effects of ascorbyl palmitate on cell membranes have only been demonstrated in the test tube. Taking ascorbyl palmitate orally probably doesn't result in any significant incorporation into cell membranes because most of it appears to be hydrolyzed (broken apart into palmitate and ascorbic acid) in the human digestive tract before it is absorbed. The ascorbic acid released by the hydrolysis of ascorbyl palmitate appears to be as bioavailable as ascorbic acid alone (15). The presence of ascorbyl palmitate in oral supplements contributes to the ascorbic acid content of the supplement and probably helps protect fat-soluble antioxidants in the supplement. The roles of vitamin C in promoting collagen synthesis and as an antioxidant have generated interest in its use on the skin (see the article, Vitamin C and Skin Health). Ascorbyl palmitate is frequently used in topical preparations because it is more stable than some aqueous (water-soluble) forms of vitamin C (16). Ascorbyl palmitate is also marketed as vitamin C ester," which should not be confused with Ester-C® (see above).

D-Isoascorbic acid (Erythorbic acid)

Erythorbic acid is an isomer of ascorbic acid. Isomers are compounds that have the same kinds and numbers of atoms, but different molecular arrangements. The difference in molecular arrangement among isomers may result in different chemical properties. Erythorbic acid is used in the US as an antioxidant food additive and is generally recognized as safe. It has been estimated that more than 200 mg erythorbic acid per capita is introduced daily into the US food system. Unlike ascorbic acid, erythorbic acid does not appear to exert vitamin C activity, for example, it did not prevent scurvy in guinea pigs (one of the few animal species other than humans that does not synthesize ascorbic acid). However, guinea pig studies also indicated that increased erythorbic acid intake reduced the bioavailability of ascorbic acid by up to 50%. In contrast, a series of studies in young women found that up to 1,000 mg/day of erythorbic acid for as long as 40 days was rapidly cleared from the body and had little effect on the bioavailability of ascorbic acid, indicating that erythorbic acid does not diminish the bioavailability of ascorbic acid in humans at nutritionally relevant levels of intake (17).

Other formulations of vitamin C

PureWay-C® is composed of vitamin C and lipid metabolites. Two cell culture studies using PureWay-C® have been published by the same investigators (18, 19), but *in vivo* data are currently lacking. A small study in healthy adults found that serum levels of vitamin C did not differ when a single oral dose (1 gram) of either PureWay-C® or ascorbic acid was administered (20).

Another formulation of vitamin C, liposomal-encapsulated vitamin C (e.g., Lypo-spheric™ vitamin C) is now commercially available. One report suggested that liposomal-encapsulated vitamin C may be better absorbed than the vitamin in a non-encapsulated form (21).

Large-scale, pharmacokinetic studies are needed to determine how the bioavailability of these vitamin C formulations compares to that of ascorbic acid.

Pauling Recommendation

Difference Between Dr. Linus Pauling's Recommendations and the LPI's Recommendation for Vitamin C Intake

Dr. Pauling, for whom the Linus Pauling Institute has great respect, based his own recommendations for vitamin C largely on theoretical arguments. In developing his recommendations, he used cross-species comparisons, evolutionary arguments, the concept of biochemical individuality, and the amount of vitamin C likely consumed in a raw plant food diet. Using this approach, Dr. Pauling suggested in the early 1970s that the optimum daily intake may be about 2,000 milligrams of vitamin C and that everyone should get at least 200 to 250 mg/day. In a 1974 radio interview, he noted that "the first 250 mg is more important than any later 250 mg. The first 250 mg leads you up to the level where the blood is saturated. You can achieve a higher volume [concentration] in the blood by a larger intake, but you get much better improvement for the first 250 mg than for additional grams." Dr. Pauling significantly increased his recommendation in his 1986 book *How To Live Longer and Feel Better*. At the Linus Pauling Institute, we have based our vitamin C recommendations on the current body of scientific evidence, which is significantly greater than it was at Pauling's time but remains incomplete owing to the many diverse functions of vitamin C in the human body that have yet to be fully understood.

In this context, it is important to note that data from the National Institutes of Health (NIH) have indicated that vitamin C levels in plasma and circulating cells become fully saturated at intakes of about 400 mg/day in young, healthy nonsmokers. These observations are consistent with other data that intakes of about 400 mg/day are associated with reduced risk of heart disease. While these NIH studies are the best we currently have regarding the pharmacokinetics of vitamin C in the human body, they have numerous limitations, including the fact that they are based on a small number of young, healthy men and women. We currently do not know how much vitamin C is required to achieve saturation of cells and tissues in children, older adults, and diseased or stressed individuals. A meta-analysis of 36 studies on the relationship between vitamin C intake and plasma concentrations found that the elderly require a substantially higher daily intake of vitamin C to attain plasma concentrations that younger adults achieve at a lower intake. Additionally, work by Linus Pauling Institute investigators has shown that cellular uptake of vitamin C declines with age, supporting the notion that vitamin C requirements are increased in the elderly.

Therefore, the Linus Pauling Institute's intake recommendation of 400 mg/day of vitamin C for generally healthy adults takes into account the currently available epidemiological, biochemical, and clinical evidence, while acknowledging the extremely low toxicity of vitamin C and the incomplete information regarding optimum intake. It should also be noted that the Linus Pauling Institute's recommendation is strictly directed towards prevention of disease in healthy individuals, not treatment of disease. Thus, individuals suffering from certain diseases may require substantially larger amounts of vitamin C to achieve optimum body levels or derive therapeutic benefits, areas that were of great interest to Linus Pauling and need to be further explored.

Summary

- Vitamin D can be synthesized in the skin upon exposure to sunlight and is then metabolized in the liver and kidney to the metabolically active form called 1α,25-dihydroxyvitamin D. Through binding to the vitamin D receptor (VDR), 1α,25-dihydroxyvitamin D can regulate the expression of hundreds of genes involved in skeletal and other biological functions. *(More information)*
- Vitamin D is essential for maintenance of bone mineralization through the regulation of calcium and phosphorus homeostasis. Vitamin D also exhibits many non-skeletal effects, particularly on the immune, endocrine, and cardiovascular systems. *(More information)*
- Vitamin D is important for normal bone development and maintenance. Severe vitamin D deficiency causes rickets in children and osteomalacia in adults. *(More information)*
- Secondary hyperparathyroidism due to vitamin D insufficiency can increase bone breakdown and precipitate osteoporosis. Randomized clinical trials indicate that supplementation with at least 800 IU/day of vitamin D may reduce the risk of falls and fractures in older individuals. *(More information)*
- Vitamin D can regulate cell differentiation and growth by binding to the vitamin D receptor found in most body cells. Observational studies have reported associations between low sun exposure, poor vitamin D status, and increased risk of developing colorectal and breast cancer. Randomized controlled trials are needed to evaluate whether cancer prevention may benefit from vitamin D supplementation. *(More information)*
- Various observational studies have reported inverse associations between vitamin D status and the susceptibility or severity of autoimmune diseases, including type 1 diabetes mellitus, multiple sclerosis, rheumatoid arthritis, and systemic lupus erythematosus. *(More information)*
- Current evidence from observational studies suggests an inverse relationship between circulating vitamin D concentrations and risk of type 2 diabetes mellitus. It is not yet known whether correcting vitamin D deficiency in individuals with glucose intolerance can decrease the risk of progression to type 2 diabetes mellitus. *(More information)*
- Randomized clinical trials are currently investigating whether vitamin D supplementation can limit cognitive deterioration and disease progression in subjects with neurodegenerative disease. *(More information)*
- Vitamin D insufficiency in pregnant women may be associated with several adverse effects for the mother and newborn. Safety and benefits of vitamin D supplementation during pregnancy both need to be evaluated in clinical trials. *(More information)*
- Observational studies have documented an association between vitamin D deficiency and increased incidence and severity of the coronavirus disease, COVID-19. *(More information)*
- Preliminary studies have shown that vitamin D supplementation may offer promising improvements in the management of atopic dermatitis (eczema) and Crohn's disease. *(More information)*

Vitamin D is a fat-soluble vitamin that regulates calcium homeostasis and is vital for bone health (1). While it can also be obtained from dietary sources or supplements, vitamin D$_3$ (cholecalciferol) is synthesized in the human skin from 7-dehydrocholesterol upon exposure to ultraviolet-B (UVB) radiation from sunlight (see the separate article on Vitamin D and Skin Health). Vitamin D$_2$ (ergocalciferol) is a vitamin D analog photosynthesized in plants, mushrooms, and yeasts; vitamin D$_2$ is also sometimes used in vitamin D food fortification (2). When vitamin D$_3$ in skin is inadequate due to insufficient exposure to UVB radiation, oral intake of vitamin D is necessary to meet vitamin D requirements.

Function

Vitamin D metabolism

Cholecalciferol and ergocalciferol are biologically inactive precursors of vitamin D and must be converted to biologically active forms in the liver and kidneys (**Figure 1**). Indeed, following dietary intake or synthesis in the epidermis of skin after UVB exposure, both forms of vitamin D enter the circulation and are transported to the liver by the vitamin D-binding protein (and to a lesser extent by albumin). In hepatocytes (liver cells), vitamin D is hydroxylated to form 25-hydroxyvitamin D (calcidiol; calcifediol). Exposure to sunlight or dietary intake of vitamin D increases serum concentrations of 25-hydroxyvitamin D. 25-Hydroxyvitamin D constitutes the major circulating form of vitamin D, and the sum of 25-hydroxyvitamin D$_2$ and 25-hydroxyvitamin D$_3$ concentrations in serum is used as an indicator of vitamin D nutritional status (3). The renal 25-hydroxyvitamin D$_3$-1α-hydroxylase enzyme (also known as CYP27B1) eventually catalyzes a second hydroxylation that converts 25-hydroxyvitamin D to 1α,25-dihydroxyvitamin D (calcitriol). The production of 1α,25-dihydroxyvitamin D in the kidneys is regulated by several factors, including serum phosphorus, calcium, parathyroid hormone (PTH), fibroblast growth factor-23 (FGF-23), and 1α,25-dihydroxyvitamin D itself. While the kidney is the main source of 1α-hydroxylase activity, extra-renal production of 1α,25-dihydroxyvitamin D has also been demonstrated in a variety of tissues, including skin, parathyroid gland, breast, colon, prostate, as well as cells of the immune system and bone cells (2). Most of the physiological effects of vitamin D in the body are related to the activity of 1α,25-dihydroxyvitamin D (4). Various forms of vitamin D are listed in **Figure 1**.

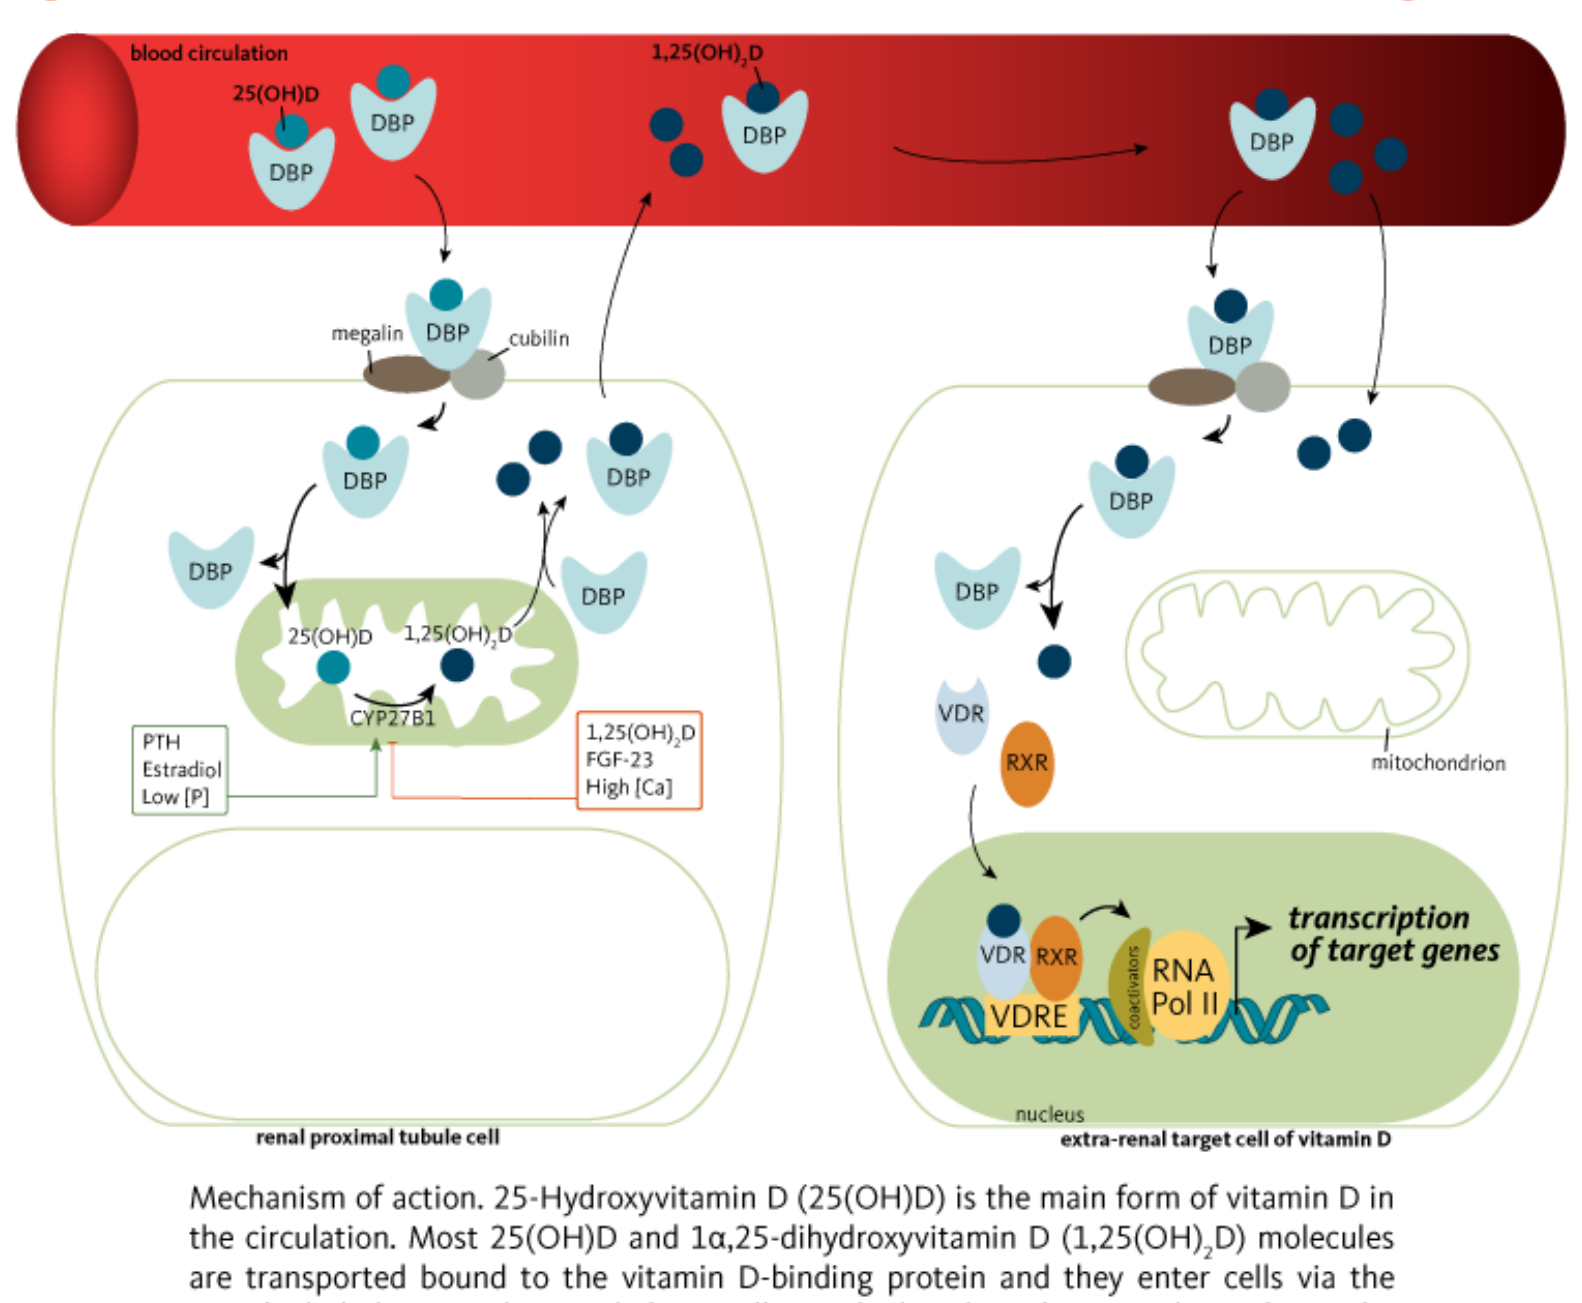
Vitamin D synthesis. Previtamin D$_3$ is synthesized in the upper layers of the skin from 7-dehydrocholesterol by the action of ultraviolet light (UVB). A nonenzymatic conversion of previtamin D$_3$ into vitamin D$_3$ (cholecalciferol) then occurs in lower layers of the skin. Vitamin D$_3$ is quickly transported to adipose tissue for storage or liver for activation. In liver cells, several cytochrome P450 (CYP) enzymes can catalyze the 25-hydroxylation of vitamin D$_3$ (or plant-based vitamin D$_2$ or ergocalciferol). The product of this step, 25-hydroxyvitamin D$_3$, is converted into the active form of vitamin D$_3$, 1α,25-dihydroxyvitamin D, in a reaction catalyzed by CYP27B1. This 1α-hydroxylation takes place primarily in the kidney.

[Figure 1 - Click to Enlarge]

Mechanisms of action

Most, if not all, actions of vitamin D are mediated through a nuclear transcription factor known as the vitamin D receptor (VDR) (**Figure 2**) (5). Upon entering the nucleus of a cell, 1α,25-dihydroxyvitamin D binds to the VDR and recruits another nuclear receptor known as retinoid X receptor (RXR). In the presence of 1α,25-dihydroxyvitamin D, the VDR/RXR complex binds small sequences of DNA known as vitamin D response elements (VDREs) and initiates a cascade of molecular interactions that modulate the transcription of specific genes. Thousands of VDREs have been identified throughout the genome, and VDR activation by 1α,25-dihydroxyvitamin D is thought to directly and/or indirectly regulate 100 to 1,250 genes (6).

Figure 2. Conversion to the Active Form of Vitamin D and VDR-mediated Gene Regulation



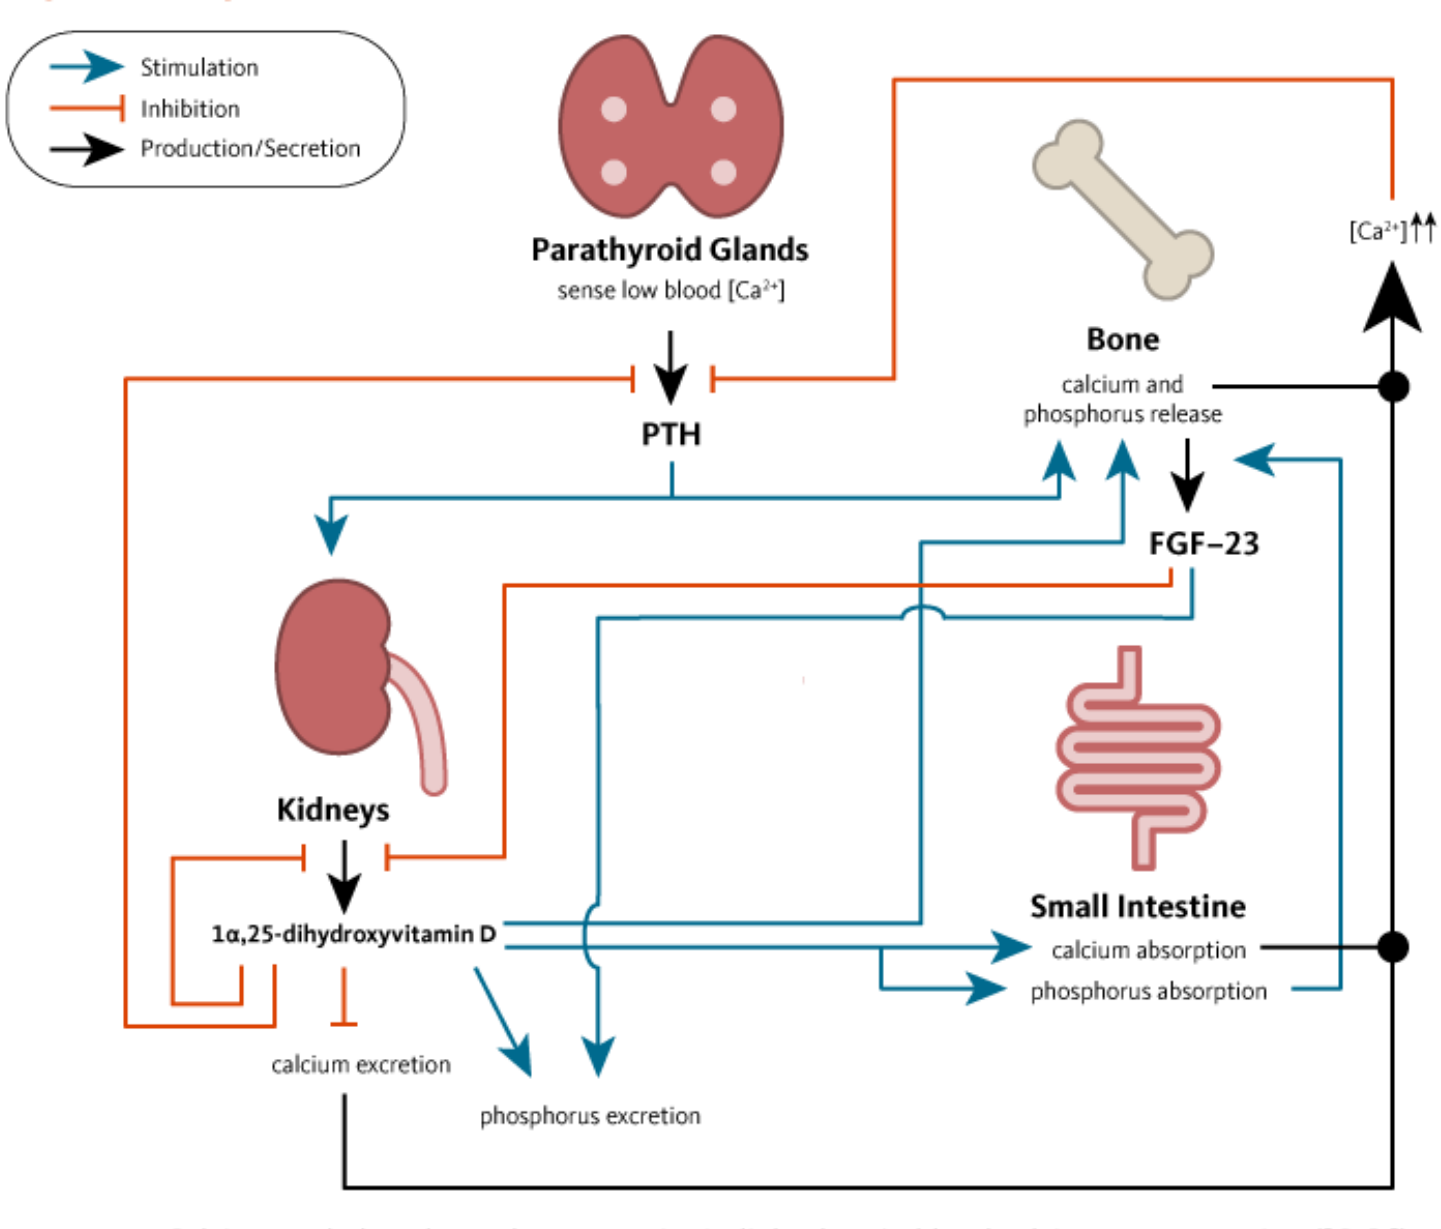
Mechanism of action. 25-Hydroxyvitamin D (25(OH)D) is the main form of vitamin D in the circulation. Most 25(OH)D and 1α,25-dihydroxyvitamin D (1,25(OH)$_2$D) molecules are transported bound to the vitamin D-binding protein and they enter cells via the megalin/tubulin complex. In kidney cells, 1α-hydroxylase (CYP27B1) catalyzes the conversion of 25(OH)D into 1,25(OH)$_2$D. Parathyroid hormone (PTH), estradiol, and low phosphorus concentration ([P]) stimulate this reaction, whereas 1,25(OH)$_2$D, fibroblast growth factor-23 (FGF-23), and high calcium concentration ([Ca]) inhibit it. 1,25(OH)$_2$D enters the circulation and is transported to extra-renal target tissues where it can regulate gene expression. In the nucleus of target cells, 1,25(OH)$_2$D binds to the vitamin D receptor (VDR), which heterodimerizes with the retinoid X receptor (RXR). VDR-RXR binds to vitamin D response elements (VDRE) in the promoter of vitamin D target genes. *25(OH)D, 25-hydroxyvitamin D; 1,25(OH)$_2$D, 1α,25-dihydroxyvitamin D; [Ca], calcium concentration; CYP2R1, 1α-hydroxylase; DBP, vitamin D-binding protein; FGF-23, fibroblast growth factor-23; PTH, parathyroid hormone; [P], phosphorus concentration; RNA Pol II, RNA polymerase II; RXR, retinoid X receptor; VDR, vitamin D nuclear receptor; VDRE, vitamin D response element.*

[Figure 2 - Click to Enlarge]

Calcium balance

Maintenance of serum calcium concentrations within a narrow range is vital for normal functioning of the nervous system, as well as for bone growth and maintenance of bone density. Vitamin D is essential for the efficient utilization of calcium by the body (1). The parathyroid glands sense serum calcium concentrations and secrete parathyroid hormone (PTH) if calcium concentrations decrease below normal (**Figure 3**). Elevations in PTH stimulate the activity of the 25-hydroxyvitamin D$_3$-1α-hydroxylase enzyme in the kidney, resulting in the increased production of 1α,25-dihydroxyvitamin D. The active vitamin D form, 1α,25-dihydroxyvitamin D, is released into the circulation and transported to target tissues. Within target cells, 1α,25-dihydroxyvitamin D binds to and induces the activation of VDR, which leads to changes in gene expression that normalize serum calcium by (1) increasing the intestinal absorption of dietary calcium, (2) increasing the reabsorption of calcium filtered by the kidneys, and (3) mobilizing calcium from bone when there is insufficient dietary calcium to maintain normal serum calcium concentrations (7).

Figure 3. Regulation of Calcium and Phosphorus Homeostasis



Calcium and phosphorus homeostasis. A slight drop in blood calcium concentration ([Ca^{2+}]) results in the secretion of parathyroid hormone (PTH) by the parathyroid glands. PTH simulates the activity of CYP27B1 (25-hydroxyvitamin D-1α-hydroxylase enzyme) that catalyzes the hydroxylation of 25-hydroxyvitamin D into 1α,25-dihydroxyvitamin D. This active form of vitamin D (i) increases the reabsorption of calcium filtered by the kidneys and stimulates phosphorus excretion, (ii) increases the intestinal absorption of both calcium and phosphorus, and (iii) mobilizes calcium (and phosphorus) from bone when dietary calcium intake is insufficient. PTH also stimulates bone resorption that releases calcium and phosphorus. 1α,25-dihydroxyvitamin D inhibits its own production, as well as PTH synthesis, via negative feedback loops. FGF-23 is secreted by bone-forming cells (osteoblasts) in response to an increase in phosphorus intake. FGF-23 inhibits the synthesis of 1α,25-dihydroxyvitamin D and promotes phosphorus excretion in the urine.
[Ca^{2+}], calcium concentration; FGF-23, fibroblast growth factor-23; PTH, parathyroid hormone.

[Figure 3 - Click to Enlarge]

Phosphorus balance

The regulations of calcium and phosphorus homeostasis are closely related, and the calciotropic hormones, PTH and 1α,25-dihydroxyvitamin D, can also control serum phosphorus. Specifically, 1α,25-dihydroxyvitamin D increases intestinal phosphorus absorption by stimulating the expression of a sodium-phosphate cotransporter in the small intestine. While PTH increases urinary excretion of phosphorus by reducing reabsorption in the kidney, it is not yet clear whether 1α,25-dihydroxyvitamin D can directly regulate renal phosphorus transport. The phosphaturic hormone fibroblast growth factor-23 (FGF-23), secreted by osteoblasts (bone-forming cells), limits the production of 1α,25-dihydroxyvitamin D by inhibiting 25-hydroxyvitamin D-1α-hydroxylase (**Figure 3**) (reviewed in 8).

Cell differentiation

Cells that are dividing rapidly are said to be proliferating. Differentiation results in the specialization of cells for specific functions. In general, differentiation of cells leads to a decrease in proliferation. While cellular proliferation is essential for growth and wound healing, uncontrolled proliferation of cells with certain mutations may lead to cancer. The active form of vitamin D, 1α,25-dihydroxyvitamin D, inhibits proliferation and stimulates the differentiation of cells through binding to the VDR (1).

Immunity

Acting through the VDR, 1α,25-dihydroxyvitamin D is a potent immune system modulator. The VDR is expressed by most cells of the immune system, including regulatory T cells and antigen-presenting cells, such as dendritic cells and macrophages (9). Under specific circumstances, monocytes, macrophages, and T cells can express the 25-hydroxyvitamin D$_3$-1α-hydroxylase enzyme and produce 1α,25-dihydroxyvitamin D, which acts locally to regulate the immune response (10, 11). There is considerable scientific evidence that 1α,25-dihydroxyvitamin D has a variety of effects on immune system function, which may enhance innate immunity and inhibit the development of autoimmunity (12). Conversely, vitamin D deficiency may compromise the integrity of the immune system and lead to inappropriate immune responses (see Autoimmune diseases).

Insulin secretion

The VDR is expressed by insulin-secreting cells of the pancreas, and the results of animal studies suggest that 1α,25-dihydroxyvitamin D plays a role in insulin secretion under conditions of increased insulin demand (13, 14). Cross-sectional and prospective studies suggest that insufficient vitamin D status may have an adverse effect on insulin secretion and glucose tolerance in type 2 diabetes mellitus (noninsulin-dependent diabetes mellitus) (reviewed in 15).

Blood pressure regulation

The renin-angiotensin system plays an important role in the regulation of blood pressure (16). Renin is an enzyme that catalyzes the cleavage (splitting) of a small peptide (angiotensin I) from a larger protein (angiotensinogen) produced in the liver. Angiotensin-converting enzyme (ACE) catalyzes the cleavage of angiotensin I to form angiotensin II, a peptide that can increase blood pressure by inducing the constriction of small arteries and by increasing sodium and water retention. The rate of angiotensin II synthesis is dependent on renin (17). Research in mice lacking the gene encoding the VDR indicates that 1α,25-dihydroxyvitamin D decreases the expression of the gene encoding renin through its interaction with the VDR (18). Since inappropriate activation of the renin-angiotensin system can contribute to the development of hypertension, achieving adequate vitamin D status may be important for decreasing the risk of high blood pressure (see Hypertension).

Deficiency

In vitamin D deficiency, calcium absorption cannot be increased enough to satisfy the body's calcium needs (4). Consequently, PTH production by the parathyroid glands is increased and calcium is mobilized from the skeleton to maintain normal serum calcium concentrations — a condition known as secondary hyperparathyroidism. Although it has long been known that severe vitamin D deficiency has serious consequences for bone health, research suggests that less obvious states of vitamin D deficiency are common and increase the risk of osteoporosis and various other health problems (see Disease Prevention).

Severe vitamin D deficiency

Rickets

In infants and children, severe vitamin D deficiency results in the failure of bone to mineralize. The process of mineralization, which involves the production of crystals of calcium phosphate by bone-forming cells, determines the hardness and strength of bones. Vitamin D deficiency severely affects rapidly growing bones. The growth plates of bones continue to enlarge, but in the absence of adequate mineralization, weight-bearing limbs (arms and legs) become bowed. In infants, rickets may result in delayed closure of the fontanels (soft spots) in the skull, and the rib cage may become deformed due to the pulling action of the diaphragm. In severe cases, low serum calcium concentrations (hypocalcemia) may cause seizures. Although fortification of food has led to complacency regarding vitamin D deficiency, nutritional rickets is still being reported throughout the world (19, 20).

Osteomalacia

Although adult bones are no longer growing, they are in a constant state of turnover, or "remodeling." In adults with severe vitamin D deficiency, the collagenous bone matrix is preserved, but bone mineral is progressively lost, resulting in a softening of bones (osteomalacia), bone pain, and increased risk of osteoporosis (21).

Muscle weakness and pain

Vitamin D deficiency causes muscle weakness and pain in children and adults. Muscle pain and weakness were prominent symptoms of vitamin D deficiency in a study of Arab and Danish Muslim women living in Denmark (22). In a cross-sectional study of 150 consecutive patients referred to a clinic in Minnesota for the evaluation of persistent, nonspecific musculoskeletal pain, 93% had serum 25-hydroxyvitamin D concentrations equal to or below 20 ng/mL, with a mean concentration of 12.1 ng/mL, which is indicative of vitamin D insufficiency (23). Loss of muscle strength greatly contributes to increased risk of falling and bone fractures, especially in older people (24). In addition, long-term vitamin D insufficiency may be a contributing factor to osteoporosis in the elderly (see Osteoporosis).

Risk factors for vitamin D deficiency

Both environmental factors and cultural practices result in variations in vitamin D status:

- Environmental conditions: Geographical locations, including latitude and altitudes, and atmospheric conditions (e.g., air pollution, presence of clouds) greatly influence the intensity of UVB radiation that reaches the ground. Seasonal changes also affect the quality and quantity of UVB rays and thus vitamin D production in skin (25-27).
- Concealed clothing style: In a study of 2,032 Middle Eastern women, who wore a headscarf or covered all skin for religious or cultural reasons, 96% had serum 25-hydroxyvitamin D concentrations less than 20 ng/mL, and 60% had vitamin D concentrations below 12 ng/mL (28). Rickets and osteomalacia are not uncommon in the Middle East and North African regions where children and women cover the majority or all of their skin whenever outside (29).
- Sun safety measures: Sun protection practices, including limiting sun exposure, wearing protective clothing and hats, and applying sunscreens, hinder skin exposure to sunlight and thus result in lower vitamin D$_3$ production and circulating vitamin D metabolites unless there is adequate oral intake. Of note, the application of sunscreen (2 mg/cm^2) with a sun protection factor (SPF) of 10 reduces UVB radiation by 90% (30).
- Exclusively breast-fed infants: Infants who are exclusively breast-fed and do not receive vitamin D supplementation are at high risk for vitamin D deficiency, particularly if they have dark skin and/or receive little sun exposure (19). Human milk generally provides 10 to 80 IU of vitamin D per liter (L), which corresponds to 0.2 to 1.5 g/day (8 to 60 IU/day) when using an average daily milk intake of 0.75 L (25 oz) (31). The American Academy of Pediatrics recommends that all breast-fed and partially breast-fed infants be given an oral vitamin D supplement of 400 IU/day (19). Maternal vitamin D supplementation during breast-feeding may contribute to improved vitamin D status of the breast-fed infant, especially in populations with a high prevalence of vitamin D deficiency (32). Older infants and toddlers exclusively fed milk substitutes (e.g., soy-based formulas) and weaning foods that are not vitamin D fortified are at risk for vitamin D deficiency (33).

The efficiency of vitamin D synthesis, absorption, and metabolism also depends on a variety of biological factors:

- Skin pigmentation: People with a dark complexion synthesize less vitamin D on exposure to sunlight than those with light-colored skin (34). A national US survey reported average serum 25-hydroxyvitamin D concentrations of 28.1 ng/mL, 21.6 ng/mL, and 16.9 ng/mL in Caucasian, Mexican American, and African American adults aged ≥20 years old, respectively (25).
- Genetic variations: An international, multicenter, genome-wide association study (GWAS) of 15 cohorts, including ~30,000 participants of European descent — known as the SUNLIGHT [Study of Underlying Genetic Determinants of Vitamin D and Highly Related Traits] consortium — identified common variations (called polymorphisms) in genes involved in cholesterol synthesis, hydroxylation, and vitamin D transport that influence vitamin D status (35). While genetic determinants of low vitamin D status are being identified in populations of European (36, 37) and Asian descent (38, 39), genome-wide association studies are needed in populations of African descent.
- Older age: The elderly have reduced capacity to synthesize vitamin D in skin when exposed to UVB radiation and are more likely to stay indoors or use sunscreen, which prevents vitamin D synthesis. It has been estimated that across Canada, the US, and Europe, the prevalence of vitamin D deficiency ranges between 20%-100% in free-living elderly (40). Moreover, institutionalized adults who are not supplemented with vitamin D are at extremely high risk of vitamin D deficiency (41, 42).
- Chronic kidney disease (CKD): Vitamin D deficiency in patients with impaired renal function is due to a reduced synthesis of 1α,25-dihydroxyvitamin D and an increased loss of 25-hydroxyvitamin D in urine (43).
- Fat malabsorption syndromes: Vitamin D deficiency is common among people with cystic fibrosis and both cholestatic and non-cholestatic liver diseases due to decreased absorption of dietary vitamin D and impaired conversion of vitamin D to 25-hydroxyvitamin D (reviewed in 44).
- Inflammatory bowel disease: People with inflammatory bowel disease like Crohn's disease appear to be at increased risk of vitamin D deficiency, especially those who have had small bowel resections (45).
- Obesity: Obesity (body mass index ≥30 kg/m^2) increases the risk of vitamin D deficiency (46). Once vitamin D is synthesized in the skin or ingested, it can be sequestered in body fat stores, making it less bioavailable to people with higher body fat mass. Moreover, vitamin D supplementation trials have shown that obese people reached much lower serum 25-hydroxyvitamin D concentrations compared to normal weight (BMI <25 kg/m^2) participants with equivalent oral dosages (47).
- Magnesium deficiency: Recent findings suggest that high magnesium intakes may reduce the risk of vitamin D insufficiency. Magnesium regulates the activity of critical enzymes in vitamin D metabolism, which would explain how magnesium deficiency negatively affects vitamin D status (48).

Assessing vitamin D nutritional status

Growing awareness that vitamin D insufficiency has serious health consequences beyond rickets and osteomalacia highlights the need for accurate assessment of vitamin D nutritional status. It is currently agreed that the measurement of total serum 25-hydroxyvitamin D concentration (1 ng/mL corresponding to 2.5 nmol/L) is the best indicator to evaluate vitamin D status. However, high-quality evidence is still needed to ensure that the current cutoff values are optimal to define states of insufficiency and deficiency (40). Moreover, only recently, efforts have been made toward the standardization of commercially and laboratory-developed 25-hydroxyvitamin D assays, such that guidelines have been developed using largely unstandardized research data (49). Although laboratory reference values for sufficient vitamin D status were initially based on serum 25-hydroxyvitamin D concentrations from cohorts of healthy individuals, additional studies have suggested that health-based cutoff values aimed at preventing secondary hyperparathyroidism and bone loss should be considerably higher. Indeed, while it is considered that serum 25-hydroxyvitamin D concentrations less than 8 to 10 ng/mL (20 to 25 nmol/L) indicate severe deficiency associated with rickets and osteomalacia, several studies have observed that PTH concentrations (50, 51) and calcium absorption (52) were not optimized with serum 25-hydroxyvitamin D concentrations below 32 ng/mL (80 nmol/L).

Yet, more recent studies have failed to find threshold values of serum 25-hydroxyvitamin D concentrations in relation to PTH suppression and optimal calcium absorption. On the one hand, a cross-sectional analysis of 312,962 clinical samples did not find any evidence of threshold for PTH suppression in the well-fitted curve displaying the inverse association between paired measurements of serum PTH and 25-hydroxyvitamin D, even with 25-hydroxyvitamin D concentrations beyond 70 ng/mL (175 nmol/L) (53). This contradicted an analysis of the US National Health and Nutrition Examination Survey (NHANES 2003-2006) that estimated maximum PTH suppression for 25-hydroxyvitamin D concentrations of 40 ng/mL (100 nmol/L) and above (54). In addition, both studies identified evidence of mild hyperparathyroidism (serum PTH >65 pg/mL) in individuals with serum 25-hydroxyvitamin D concentrations well beyond 20 ng/mL (50 nmol/L), questioning the use of serum PTH as a sensible indicator of vitamin D insufficiency (53, 54). On the other hand, a randomized, placebo-controlled trial in postmenopausal women with vitamin D insufficiency (serum 25-hydroxyvitamin D <20 ng/mL) supplemented with daily vitamin D$_3$ doses from 400 to 4,800 IU found little change (6%) in calcium absorption over a normal 25-hydroxyvitamin D concentration range of 20 to 66 ng/mL (55).

The current cutoffs proposed by the Institute of Medicine (IOM) are as follows: deficiency as serum 25-hydroxyvitamin D values <12 ng/mL (<30 nmol/L), insufficiency as serum 25-hydroxyvitamin D values of 12 to 19 ng/mL (30 to 49 nmol/L), and sufficiency as serum 25-hydroxyvitamin D values of 20 to 50 ng/mL (50 to 125 nmol/L) (56). The dietary reference intakes (EAR, RDA) set by the IOM are based on achieving circulating 25-hydroxyvitamin D concentrations (20 to 50 ng/mL) that are adequate to maintain bone health and optimal calcium absorption (57).

Yet, considering the potential role of circulating concentrations lower than 30 ng/mL in the burden of many chronic diseases (6), the US Endocrine Society has suggested to define cutoff values as follows: deficiency as serum 25-hydroxyvitamin D values ≤20 ng/mL (≤50 nmol/L), insufficiency as serum 25-hydroxyvitamin D values of 21 to 29 ng/mL (51 to 74 nmol/L), and sufficiency as serum 25-hydroxyvitamin D values of 30 to 100 ng/mL (75 to 250 nmol/L) (40). This alternate target range is supported by some observational studies, but it is not based on data from randomized controlled trials (see Disease Prevention) (47). With these latter cutoff values, studies from across the world have estimated that hypovitaminosis D is widespread and that children and adults of all ages are equally at risk of insufficiency and deficiency (58). Data from supplementation studies indicate that vitamin D intakes of at least 800 to 1,000 IU/day are required by adults living in temperate latitudes to achieve serum 25-hydroxyvitamin D concentrations of at least 30 ng/mL (75 nmol/L) (40).

Finally, total serum 25-hydroxyvitamin D concentrations may not always adequately reflect vitamin D bioavailability (59), and additional evidence is needed to improve the determination of vitamin D status in different ethnic populations.

The Recommended Dietary Allowance (RDA)

In 2010, the Food and Nutrition Board (FNB) of the IOM set a Recommended Dietary Allowance (RDA) based on the amount of vitamin D needed for bone health. While the RDA was increased from the adequate intake (AI) set in 1997, the optimal levels of recommended intakes and serum 25-hydroxyvitamin D to minimize hyperthyroidism and maximize bone health in the general population remain controversial (40). The RDA for vitamin D is listed in **Table 1** by life stage and gender.

Table 1. Recommended Dietary Allowance (RDA) for Vitamin D

Life Stage	Age	Males		Females	
		µg/day	IU/day	µg/day	IU/day
Infants (AI)	0-6 months	10	400	10	400
Infants (AI)	6-12 months	10	400	10	400
Children	1-3 years	15	600	15	600
Children	4-8 years	15	600	15	600
Children	9-13 years	15	600	15	600
Adolescents	14-18 years	15	600	15	600
Adults	19-70 years	15	600	15	600
Adults	71 years and older	20	800	20	800
Pregnancy	all ages	-	-	15	600
Breast-feeding	all ages	-	-	15	600

Disease Prevention

Mortality

In a nine-year follow-up analysis of the Third US National Health and Nutrition Examination Survey (NHANES III) that included 15,099 participants (of which 77% were Caucasians), serum concentrations of 25-hydroxyvitamin D — standardized as per the methodology developed by the Vitamin D Standardization Program [VDSP] — were examined in relation to mortality. The analysis suggested an increase in all-cause mortality with decreasing serum 25-hydroxyvitamin D concentrations <16 ng/mL (60). In contrast, the risk of all-cause mortality varied little for baseline serum 25-hydroxyvitamin D concentrations in the range of 16 to 40 ng/mL (60). Similar results were obtained in a meta-analysis of eight prospective cohort studies that considered the relationship between standardized 25-hydroxyvitamin D concentrations and mortality during a median follow-up period of 10.5 years. The risk of death was found to be 19% higher with 25-hydroxyvitamin D concentrations between 12 and 15.99 ng/mL and 56% higher with concentrations <12 ng/mL compared to the risk associated with concentrations between 30 and 39.99 ng/mL (61). A meta-analysis of 73 prospective cohort studies, including >800,000 participants, found that the lowest versus highest tertile of serum 25-hydroxyvitamin D concentrations was associated with greater risks of all-cause mortality (+35%), mortality due to cardiovascular disease (+35%), and mortality due to cancer (+14%) (62). Yet, a Mendelian randomization analysis — which limits bias due to confounding and reverse causation (63) — of data from three large Danish cohorts of 95,766 adults found a significant association of genetically low plasma 25-hydroxyvitamin D concentrations with all-cause and cancer-related mortality, but not with cardiovascular disease-related mortality (64). Finally, two meta-analyses of randomized controlled trials have suggested a modest reduction in all-cause mortality in older people supplemented with vitamin D and calcium, but not vitamin D alone (62, 65). Additional placebo-controlled trials need to examine further whether supplementation with vitamin D alone or in combination with calcium might help prevent premature death in replete individuals.

Osteoporosis

Vitamin D status, osteoporosis, and risk of fracture

Although the causes of osteoporosis are multifactorial, vitamin D insufficiency can be an important etiological factor in older adults. Osteoporosis affects one-third of women aged 60 to 70 years and two-thirds of women aged 80 years and above (66). A multinational (18 different countries with latitudes ranging from 64 degrees north to 38 degrees south) survey of more than 2,600 postmenopausal women with osteoporosis revealed that 31% of subjects had 25-hydroxyvitamin D concentrations <20 ng/mL (50 nmol/L) (67). In addition, a case-control study that included 111 hip fracture patients and 73 controls (median age, 83 years) found that lower serum concentrations of both 25-hydroxyvitamin D and vitamin K$_1$ in patients compared to controls were associated with an increased risk of hip fracture (68). Without sufficient vitamin D from sun exposure or dietary intake, intestinal calcium absorption can be significantly reduced. This increases PTH secretion by the parathyroid glands; sustained PTH elevation may result in increased bone resorption, which in turn may increase the risk of osteoporotic fracture (69).

Vitamin D supplementation and bone mineral density

The progressive loss of bone mineral density (BMD) leading to osteopenia (pre-osteoporosis) and osteoporosis is commonly observed in older adults, especially the elderly. The results of a meta-analysis of 23 randomized controlled trials with more than 4,000 participants (mean age, 59 years) showed little evidence for an effect of vitamin D supplementation on BMD at any of the five skeletal sites examined, including lumbar spine, femoral neck, trochanter, forearm, and total body. A significant increase in BMD was reported only at the femoral neck (70). It was, however, suggested that individuals in this age group would have adequate calcium intake and thus normal bone metabolism, explaining the lack of an effect of vitamin D in strengthening bone mass (71). Conversely, in older individuals, vitamin D supplementation is essential to correct and maintain adequate concentrations of serum 25-hydroxyvitamin D and to prevent secondary hyperparathyroidism and BMD loss (72).

Vitamin D supplementation and risk of fracture

A prospective cohort study that followed more than 72,000 postmenopausal women in the US for 18 years found that those who consumed at least 600 IU/day of vitamin D from diet and supplements had a 37% lower risk of osteoporotic hip fracture than women who consumed less than 140 IU/day of vitamin D (73). However, daily supplementation with 400 IU of vitamin D$_3$, in combination with 1,000 mg calcium, did not significantly reduce risk of hip fracture compared to a placebo in 36,282 postmenopausal women from the Women's Health Initiative trial (74), suggesting that there might be a threshold of vitamin D intake that is necessary to observe reductions in fracture risk. Results of a genetic analysis of data from this trial also suggested that beneficial effects of vitamin D and calcium supplementation on fracture risk might be limited to women with the lowest genetic risk of low BMD (75). Yet, this trial has been questioned for reasons that include poor adherence and the fact that participants were allowed to take additional vitamin D and calcium supplements that might have confounded the results. In addition, use of hormone replacement therapy was not considered in the study of the effect of vitamin D and calcium on skeletal health in postmenopausal women despite being a major confounding factor in this population (57, 76).

Another trial, the Randomised Evaluation of Calcium Or vitamin D (RECORD) study, reported that oral supplemental vitamin D$_3$ (800 IU/day) alone, or in combination with calcium (1,000 mg/day), did not prevent the occurrence of osteoporotic fractures in elderly adults who had already experienced a low-trauma, osteoporotic fracture (77). In this latter study as well, a number of limitations, including poor adherence and/or the fact that vitamin D supplementation did not raise serum 25-hydroxyvitamin D concentrations to a level that would protect against fractures, might explain the lack of an effect (78). Despite high adherence to treatment, the incidence of non-vertebral fracture was similar in postmenopausal women supplemented with vitamin D$_3$ (initial dose of 200,000 IU followed by 100,000/month) or placebo for over three years in the Vitamin D Assessment (ViDA) trial (79).

Nevertheless, the US Preventive Services Task Force that conducted the meta-analysis of 11 randomized, placebo-controlled trials, including 52,915 older people (of whom 69% were postmenopausal women), found that the supplementation of vitamin D (300-1,000 IU/day) and calcium (500-1,200 mg/day) for up to seven years resulted in a 12% reduction in the risk of any new fracture (80). Another meta-analysis of 11 randomized, double-blind, placebo-controlled trials on the effect of vitamin D supplementation in 31,022 individuals (91% women) 65 years and older indicated that those with the highest vitamin D intake (792-2,000 IU/day) had a 30% lower risk of hip fracture and a 14% lower risk of any non-spine fracture (81). Finally, a third meta-analysis of trials that examined the effect of combined vitamin D and calcium in preventing fractures in older men and postmenopausal women also concluded that the risk of new fractures, including hip fractures, was significantly reduced in those supplemented compared to controls (82). Interestingly, the three meta-analyses have found that the prevention of fractures by supplemental vitamin D and calcium was limited to institutionalized, older people. Indeed, the risk of fracture was not significantly reduced by vitamin D in community-dwelling seniors (80-82).

Vitamin D supplementation and postural balance, muscle strength, and risk of fall

A meta-analysis of seven observational studies in 840 fallers and 1,330 non-fallers found significantly lower serum 25-hydroxyvitamin D concentrations in fallers than in non-fallers (83). Moreover, another meta-analysis of four cohorts from three observational studies reported a modest yet significant inverse association between vitamin D status and the risk of fall (83). Several randomized controlled trials have examined the impact of vitamin D supplementation on muscle strength, postural balance, or risk of fall in older subjects. A meta-analysis of these trials found limited evidence of an effect of vitamin D supplementation on muscle strength and mobility, based on only one type of test for each outcome. Nevertheless, in a recent randomized, double-blind, placebo-controlled study in 160 postmenopausal women (ages, 50-65 years) with suboptimal vitamin D status (mean serum 25-hydroxyvitamin D concentration <20 ng/mL), supplementation with 1,000 IU/day of vitamin D$_3$ significantly improved vitamin D status, as well as upper and lower limb muscle strength and postural balance parameters (84, 85). The risks of fall and recurrent falls were found to be two- to three-fold greater in women in the control group than in those supplemented with vitamin D$_3$ (85). In contrast, another 12-month randomized controlled study in 200 older adults (of which 58% had a baseline serum 25-hydroxyvitamin D concentration <20 ng/mL) showed no benefits regarding lower extremity function or odds of falling in those supplemented with 2,000 IU/day (+/- 10 µg of calcidiol) compared to those who received 800 IU/day (86). The recently published post-hoc analysis of the ViDA trial found no differences in odds of falling and number of falls reported by 5,108 community-dwelling participants (ages, 50-84 years) regardless of whether they were randomized to receive supplemental vitamin D (100,000 IU/month, i.e. ~3,350 IU/day) or a placebo for a mean 3.4 years (79). Most ViDA participants had serum 25-hydroxyvitamin D concentrations ≥20 ng/mL, which might at least partly explain the lack of an effect of vitamin D on falls (87).

Overall, the current evidence suggests that vitamin D$_3$ supplements of 800-1,000 IU/day may be helpful in reducing falls and fracture rates in older adults. In order for vitamin D supplementation to be effective in preserving bone health, adequate dietary calcium (1,000 to 1,200 mg/day) should be consumed (see the article on Calcium) (88).

Cancer

Ecologic studies first suggested an association between Northern latitudes, vitamin D deficiency, and cancer incidence (89). Since the 1980s, several prospective cohort studies have examined the association of vitamin D intake or status and various types of cancer. A 2013 systematic review and meta-analysis of 16 prospective studies, including 137,567 subjects, reported an 11% reduction in total cancer incidence and a 17% reduction in cancer mortality with each 20 ng/mL (50 nmol/L) increase in circulating 25-hydroxyvitamin D concentrations. Yet, a sex-based subgroup analysis of eight studies found an inverse association between circulating vitamin D and cancer mortality in women, but not in men (90). In addition, increasing evidence suggests that a few variations in the gene coding for the vitamin D receptor (VDR) might influence individual vitamin D status and subsequently modify the susceptibility to site-specific cancers (91) and influence cancer survival (92). Finally, many malignant tumors have been found to express the VDR, including breast, lung, skin (melanoma), colon, and bone (93), suggesting that they might be susceptible to the effects of vitamin D. Numerous experimental studies have demonstrated that biologically active forms of vitamin D, such as 1α,25-dihydroxyvitamin D and its analogs, upon binding to the VDR, can control cell fate by inhibiting proliferation and/or inducing cell differentiation or death (apoptosis) of a number of cancerous cell types (94).

Colorectal cancer

The geographic distribution of colon cancer mortality resembles the historical geographic distribution of rickets (95), providing circumstantial evidence that decreased sunlight exposure and diminished vitamin D nutritional status may be related to an increased risk of colon cancer. Evidence from observational studies has largely supported this hypothesis. A recent meta-analysis of four prospective cohort studies, four cross-sectional studies, and seven case-control studies found an inverse relationship between circulating vitamin D and incidence of colorectal adenoma — a benign tumor that may transform to become malignant (96). The analysis identified a 32% risk reduction between top versus bottom quantiles of serum 25-hydroxyvitamin D concentrations (96). Additionally, there is strong evidence from meta-analyses of prospective cohort studies to suggest that higher vitamin D intakes and serum 25-hydroxyvitamin D concentrations are associated with reductions in colorectal cancer risk (97-99). The most recent meta-analysis of four prospective cohort, 17 nested case-control, and three case-control studies found a 38% reduced risk of colorectal cancer with high versus low quantiles of circulating 25-hydroxyvitamin D concentrations (100). A dose-response analysis estimated that serum 25-hydroxyvitamin D concentrations of ~20 to 30 ng/mL (compared to ≤12 ng/mL) were associated with a 17% lower risk of colorectal cancer, and the risk was even lower (-35%) with a serum concentration of 55 ng/mL (100). An earlier dose-response analysis based on five nested case-control studies had estimated that serum 25-hydroxyvitamin D concentrations ≥33 ng/mL (compared to ≤12 ng/mL) were associated with a 50% lower risk of colorectal cancer (101).

However, in a seven-year, randomized, double-blind, placebo-controlled trial in 36,282 postmenopausal women participating in the Women's Health Initiative study, a combination of supplemental vitamin D$_3$ (400 IU/day) and calcium (1,000 mg/day) did not lower incidence of colorectal cancer (102). Another randomized controlled trial of vitamin D$_3$ supplementation (1,000 IU/day), with or without calcium supplementation (1,200 mg/day), found no reduction in the risk of colorectal adenoma recurrence over a three-to-five year period, compared to placebo, after initial adenoma removal in participants (103). Whether these daily vitamin D doses are too low to detect any effect on cancer incidence is not clear (101, 104). Additional randomized clinical trials are needed to assess whether vitamin D supplementation could help prevent colorectal cancer. Moreover, it is uncertain whether genetic variations (polymorphisms) in the sequence of genes involved in vitamin D metabolism and function can influence the relationship between vitamin D status and risk of colorectal adenoma or colorectal cancer (105-107).

Finally, growing evidence suggests that adequate vitamin D status may be linked to better survival of colorectal cancer patients. A meta-analysis of five prospective studies found a 35% reduced risk of colorectal cancer-specific mortality in cancer patients with higher serum 25-hydroxyvitamin D concentrations. A dose-response analysis estimated that every 8 ng/mL increase in 25-hydroxyvitamin D concentration was associated with a 10% decrease in colorectal cancer mortality (108).

Breast cancer

Although ecologic evidence suggests that breast cancer mortality rises with increasing latitudes and decreasing sunlight exposure (109), the most current observational data provide little support for an association between vitamin D nutritional status and risk of breast cancer. An early prospective study of women who participated in the First US National Health and Nutrition Examination Survey (NHANES I) found that Caucasian women with adequate sunlight exposure and dietary vitamin D intake had a significantly reduced risk of breast cancer 20 years later (110). Nonetheless, when this study was included in a meta-analysis with nine more recent prospective studies, there was no significant difference in the risk of developing breast cancer between the highest and lowest levels of vitamin D intakes (111). Moreover, whether an association exists between circulating vitamin D concentrations and risk of breast cancer is unclear. One between the highest and lowest levels of vitamin D intakes (111). Moreover, whether an association exists between circulating vitamin D concentrations and risk of breast cancer is unclear. One meta-analysis of 14 observational studies (9,110 cases and 16,244 controls) reported an overall risk reduction of 16% when the highest quantile of serum 25-hydroxyvitamin D concentrations was compared to the lowest. This inverse association was statistically significant in postmenopausal women but not in premenopausal women (112). Yet, another meta-analysis that included a similar set of 14 prospective studies (two studies were different) found no overall association (111). Additionally, a meta-analysis of studies conducted in patients in the early stage of breast cancer identified associations between inadequate vitamin D status and increased risks of recurrence and death (113). Evidence from randomized controlled trials is currently too limited to conclude whether vitamin D supplementation may reduce breast cancer incidence (reviewed in 114).

Nonetheless, three meta-analyses have found an inverse association between circulating vitamin D concentrations and breast cancer-related mortality (111, 115, 116). In one meta-analysis of one retrospective and five prospective cohort studies, the highest versus lowest categories of serum vitamin D concentrations was associated with a 33% reduction in mortality; a dose-response analysis found a 12% reduction per 8 ng/mL increase in serum vitamin D (115).

Finally, current evidence does not suggest that specific genetic variations in the gene coding for the VDR may influence the risk of breast cancer (117, 118).

Other types of cancer

Evidence associating vitamin D status with other types of cancer is currently limited. While incidence of prostate cancer appears to be inversely associated with the availability of sunlight, prospective cohort studies have not generally found significant relationships between serum 25-hydroxyvitamin D concentrations and subsequent risk of developing prostate cancer (119, 120). In fact, some studies have suggested an increased risk of prostate cancer with higher circulating vitamin D concentrations. For example, a nested case-control study of men (622 cases and 1,451 controls) from Scandinavia found a U-shaped relationship between serum 25-hydroxyvitamin D concentrations and prostate cancer risk. In that study, serum 25-hydroxyvitamin D concentrations of 7.6 ng/mL or lower, or 32 ng/mL or higher, were associated with increased prostate cancer risk (121). A meta-analysis of 17 nested case-control studies, three prospective cohort studies, and one retrospective cohort study found a 17% increased risk of prostate cancer in individuals in the highest versus lowest categories of blood 25-hydroxyvitamin D concentrations (122). Potential confounding factors that might explain the detection of a slight increase in prostate cancer cases in men with high circulating vitamin D concentrations have been highlighted in a recent publication (123).

Finally, recent meta-analyses of observational studies found an inverse relationship between vitamin D status and risk of lung cancer (124, 125) and bladder cancer (126, 127). Yet, in the few and often heterogeneous studies published to date, serum 25-hydroxyvitamin D concentrations were not associated with other cancer types, including non-Hodgkin's lymphoma (128), ovarian cancer (129), gastric cancer (130), or skin cancers (131).

Autoimmune diseases

Insulin-dependent diabetes mellitus (type 1 diabetes mellitus), multiple sclerosis (MS), rheumatoid arthritis (RA), and systemic lupus erythematosus (SLE) are examples of autoimmune diseases. Autoimmune diseases occur when the body mounts an immune response against its own tissue, rather than a foreign pathogen. In type 1 diabetes mellitus, insulin-producing β-cells of the pancreas are the target of an inappropriate immune response. In MS, the targets are the myelin-producing cells of the central nervous system, and in RA, the targets are the collagen-producing cells of the joints (132). SLE is characterized by the presence of a large spectrum of autoantibodies resulting in potential damage to multiple tissues (133). Autoimmune responses are mediated by immune cells called T cells. The biologically active form of vitamin D, 1α,25-dihydroxyvitamin D, has been found to modulate T cell responses, such that the autoimmune responses are diminished. Ecologic studies have found that the prevalence of autoimmune diseases (particularly for MS; 134) increases as latitude increases, suggesting that lower exposure to UVB radiation and associated decreases in skin vitamin D synthesis may play a role in the pathology of these diseases. Results of several prospective cohort studies also suggest that adequate vitamin D status at different ages (including *in utero*, early childhood, and during adolescence) could possibly decrease the risk of autoimmune diseases.

Type 1 diabetes mellitus

Lower levels of circulating vitamin D have been reported in patients newly diagnosed with type 1 diabetes mellitus compared to age- and sex-matched non-diabetic subjects (135, 136). A greater prevalence of vitamin D insufficiency and deficiency has also been observed in prediabetic children who developed multiple islet autoantibodies (antibodies against insulin-secreting pancreatic cells) compared to autoantibody-negative children. However, a prospective study that followed the cohort of prediabetic children found that their vitamin D status, defined as either insufficient, deficient, or sufficient, was not associated with rate of progression to type 1 diabetes after 5 or 10 years of follow up (137). An earlier prospective cohort study of children born in Finland during the year 1966 and followed for 30 years found that children supplemented with vitamin D during the first year of life had an 88% lower risk of developing type 1 diabetes compared to those receiving no supplementation. Moreover, children suspected of having had rickets (severe vitamin D deficiency) during the first year of life showed a significantly higher risk of developing type 1 diabetes (138). Thus, vitamin D supplementation appears protective against type 1 diabetes onset, and suboptimal vitamin D status in infancy may have long-term effects on immune responses later in life.

There are also limited data suggesting that maternal vitamin D insufficiency during pregnancy may influence the risk of type 1 diabetes in offspring. In a recent case-control study, the risk of childhood onset of type 1 diabetes was more than two-fold greater in children whose mothers had serum 25-hydroxyvitamin D concentrations <21.6 ng/mL (54 nmol/L) during the last trimester of pregnancy compared to children born from women with serum 25-hydroxyvitamin D >35.6 ng/mL (89 nmol/L) (139). Other case-control studies have found that vitamin D supplementation during pregnancy was associated with a lower risk of their children developing diabetes-related autoantibodies (140, 141). However, a larger study conducted in mothers of children at increased genetic risk for diabetes reported no association between the appearance of islet autoantibodies and/or diabetes onset in offspring in the first year of life and maternal vitamin D intake during pregnancy (142). Another case-control study failed to observe a relationship between serum 25-dihydroxyvitamin D during early pregnancy and type 1 diabetes diagnosis in offspring (143). Large prospective studies are needed to establish whether maternal vitamin D status during pregnancy can influence the risk of type 1 diabetes in offspring.

Finally, the relationship of polymorphisms in vitamin D metabolism-related genes and type 1 diabetes is currently under investigation. It has been proposed that specific polymorphisms in genes, such as *CYP27B1* (coding for 25-hydroxyvitamin D_3-1α-hydroxylase) and *VDR*, may be functionally relevant to the action of vitamin D and may thus affect disease susceptibility. In a study conducted in 8,517 children and adolescents with type 1 diabetes and 7,320 control subjects, polymorphisms in genes involved in cholesterol synthesis and vitamin D hydroxylation were linked to circulating vitamin D concentrations and diabetic status (26).

Multiple sclerosis

Low levels of sun exposure and vitamin D deficiency appear to be associated with the development of multiple sclerosis (MS). Poor vitamin D status may compromise the function of specific immune cells critical in the regulation of various immune responses and help trigger autoimmunity in MS (144). Genetic determinants of low vitamin D status have been recently linked to an increased susceptibility to adult-onset MS in a Mendelian randomization analysis of data from the Multiple Sclerosis Genetics Consortium (145). This echoed the results of several observational studies that suggested an association between vitamin D sufficiency and decreased MS risk. A retrospective study of levels of ambient UV radiation and cases of MS conducted in Australia revealed that MS incidence in offspring was inversely correlated to maternal exposure to UV during early pregnancy (146). Sun exposure was also used as a surrogate marker for vitamin D exposure in a recent case-control study that included 1,660 MS patients and 3,050 controls. The authors found that infrequent outdoor activities and the use of sunscreen during early childhood and adolescence were associated with an increased risk of developing MS later in life (147). In a cross-sectional study, sun exposure and intake of cod liver oil (rich in vitamin D) during childhood were linked to later symptom onset among veterans with relapsing MS (148). Additionally, a case-control study in US military personnel, including 257 cases of diagnosed MS, found that Caucasian subjects in the highest quintile of serum 25-hydroxyvitamin D (>39.6 ng/mL) had a 62% lower risk of developing MS compared to the lowest quintile (<25.3 ng/mL) (149). Further, in two large cohorts of over 187,000 US women followed for at least 10 years, vitamin D supplement use (≥400 IU/day) was associated with a 41% reduction in the risk of developing MS (150). Another prospective, uncontrolled study monitored incidence of relapse in relation to vitamin D status in 156 patients with relapsing-remitting MS before and after they were given supplemental vitamin D (100,000 IU/month; 6-42 months, median of 31 months), in addition to first-line immunomodulatory therapy (151). Each 4 ng/mL increase in serum 25-hydroxyvitamin D concentration was associated with a 14.9% decrease in incidence of relapse (151). In a multicenter study conducted in patients newly diagnosed with a clinically isolated syndrome (CIS) and treated with interferon (IFN)-β, vitamin D status was predictive of MS disease activity and progression. Higher serum 25-hydroxyvitamin D concentrations (≥20 ng/mL or ≥50 nmol/L) in the first year following CIS diagnosis predicted a longer time to MS diagnosis, lower number of new lesions, and lower changes in lesion and brain volume during the subsequent four years of follow-up (152). However, a retrospective study suggested that vitamin D status in patients with relapsing-remitting MS had no predictive value regarding the time to conversion to secondary progressive MS, which is characterized by a worsening of disability (153).

Clinical trials have failed to demonstrate any benefit of vitamin D supplementation, alone or in combination with IFN-β treatment, with respect to relapse rates and disability-related symptoms in MS patients (154, 155). In other trials, supplemental vitamin D_3 also failed to demonstrate immunomodulary activities (156-159). In a recent randomized, placebo-controlled trial in 53 IFN-β-treated patients with relapsing-remitting MS, supplementation with vitamin D_3 (7,000 IU/day for four weeks, followed by 14,000 IU/day until week 48) showed little effect on the proportion of some regulatory T and B lymphocytes over the 48-week study period. Vitamin D_3 only appeared to help maintain the proportion of anti-inflammatory CD4⁺ T cells — which decreased in patients given placebo — but failed to enhance their reactivity when stimulated with 1,25-dihydroxyvitamin D *in vitro* (157). In another trial, supplementation with vitamin D_3 (10,400 IU/day for three months) to patients with relapsing-remitting MS was found to reduce the proportion of pro-inflammatory IL-17-producing CD4⁺ T cells, which are thought to play a central role in MS development (160).

Rheumatoid arthritis

Vitamin D deficiency may also be implicated in the etiology and/or progression of rheumatoid arthritis (RA), although evidence is mainly from animal studies. The absence of vitamin D receptors (VDR) in genetically modified mice has been linked to higher levels of inflammation and increased susceptibility to autoimmunity (161). When transgenic mice that spontaneously develop inflammatory arthritis are also deficient in VDR, they develop a more aggressive form of chronic arthritis (162). Also, specific polymorphisms in the *VDR* gene have been linked to an increased susceptibility to RA in certain populations, although how these genetic variants influence vitamin D functionality is not fully understood (163-165). The current data, however, point to a role for vitamin D in modulating the inflammatory process that underlies many chronic diseases, including RA. Several cross-sectional studies in individuals with moderate-to-high levels of inflammation have reported either no association or an inverse association between circulating 25-hydroxyvitamin D concentration and markers of inflammation. Nonetheless, there is a lack of intervention trials to show whether vitamin D supplementation could limit inflammation and reduce disease risk (including RA) in subjects with high inflammation levels (166).

At this time, it remains unclear whether the prevalence of vitamin D deficiency is linked to RA incidence. In a large cohort study of nearly 30,000 postmenopausal US women, subjects with the highest total vitamin D intakes (≥467.7 IU/day) had a 33% lower risk of developing RA after 11 years of follow-up than those with the lowest intakes (<221.4 IU/day) (167). Yet, more recent analyses of two large cohorts of nearly 200,000 US women followed for several decades found no association between reported vitamin D dietary intakes (using food frequency questionnaires) during adolescence or adulthood and incidence of RA later in life (168, 169). Moreover, several studies that explored the relationship between circulating vitamin D and disease activity in RA patients have reported mixed results (reviewed in 170). Yet, two recent meta-analyses of observational studies found an inverse relationship between vitamin D status and disease activity in RA patients, assessed using the Disease Activity Score 28 (DAS28) (171, 172). Finally, there is a dearth of studies exploring the effect of vitamin D supplementation on disease activity in arthritis subjects. A small randomized, double-blind, placebo-controlled study in 22 RA patients failed to demonstrate improvements in disease activity and inflammation level in subjects supplemented with calcium (1,500 mg/day) and high doses of vitamin D_2 (ergocalciferol; averaging over 4,500 IU/day) for a year compared to placebo (173). Another three-month, randomized controlled trial in 41 women with early RA found no additional benefits of supplemental vitamin D_3 (one bolus dose of 300,000 IU) to standard care (methotrexate and glucocorticoids) regarding T-helper lymphocyte enumeration, cytokine production, or clinical parameters including disease activity (174). Supplemental vitamin D also failed to reduce disease recurrence rate in RA patients enrolled in two small randomized controlled trials (175, 176). Since these studies have several limitations, including small sample size, additional research is warranted.

Systemic lupus erythematosus

More prevalent and severe in non-Caucasian populations (Hispanics, African descendants, and Asians) (177), systemic lupus erythematosus (SLE) is an autoimmune disease with heterogeneous clinical manifestations. The disease can potentially affect most tissues and organs, including skin (skin rash and photosensitivity), kidneys (nephritis), and joints (arthritis). There is evidence of a role for vitamin D in the prevention of SLE in animal models (178). Interestingly, a recent meta-analysis of 11 case-control studies found that specific *VDR* polymorphisms were linked to SLE in Asians particularly (179). However, the functional relevance of such genetic variants is not known (180). Analyses of two large prospective cohort studies of nearly 200,000 US women failed to show an association between dietary vitamin D intake (measured by food frequency questionnaire) during adolescence or adulthood and incidence of SLE later in life (168, 169).

Yet, a suboptimal vitamin D status is commonly observed in subjects with SLE, and this is partly explained by the lack of sunlight exposure, which tends to aggravate disease symptoms (181, 182). Serum concentrations of 25-hydroxyvitamin D were inversely correlated with measures of disease activity in a cohort of 378 patients with SLE (183). The correction of vitamin D insufficiency with high levels of vitamin D_3 (100,000 IU/week for one month followed by 100,000 IU/month for six months) in 20 subjects with SLE was linked to a reduction in signs of immune imbalance and in levels of autoantibodies typically detected in SLE, suggesting a therapeutic value for vitamin D in disease treatment (184). Another prospective study conducted in 52 vitamin D-deficient patients with cutaneous lupus erythematosus (a type of lupus with skin disorders only) reported a reduction in disease severity in the group supplemented with vitamin D_3 (1,400 IU/day initially, followed by 800 IU/day) and calcium for one year compared to untreated patients (185). Supplementation with vitamin D_3 (200 IU/day for one year) was also able to reduce the level of inflammatory cytokines in a randomized, placebo-controlled study conducted in 267 patients with SLE (186). In another randomized, placebo-controlled trial, supplementation with vitamin D_3 (50,000 IU/week for six months) improved SLE disease activity index (SLEDAI) and European Consensus Lupus Activity Measurement (ECLAM) scores, as well as some measures of fatigue in young adults with juvenile-onset SLE (187). However, in two other recent studies, supplementation with vitamin D_3 (weekly/monthly bolus doses equivalent to ~800 to 7,000 IU/day for 6 to 24 months) improved vitamin D status in SLE patients but failed to show any benefit regarding disease activity (188, 189). While oral vitamin D administration to SLE patients is well tolerated, its efficacy remains questionable and deserves further investigation in clinical trials.

Summary

Thus, evidence from human epidemiological studies suggests that while it cannot yet be concluded that vitamin D supplementation is beneficial in prevention or treatment of autoimmune disease, it is reasonable to assume that correcting vitamin D insufficiency and maintaining sufficient levels could possibly help decrease disease risk (190).

Cardiovascular disease

Hypertension (high blood pressure)

Hypertension is a well-known risk factor for cardiovascular disease (CVD) (191). The results of observational and clinical studies suggest a role for vitamin D in lowering blood pressure, which may be partly explained by the fact that 1α,25-dihydroxyvitamin D inhibits renin synthesis (see Function). Thus, vitamin D deficiency and subsequent upregulation of the renin-angiotensin system may contribute to high blood pressure and CVD risk. It has also been suggested that elevated PTH concentrations may increase the risk of hypertension and CVD (6). Yet, in a recent prospective cohort study of 3,002 individuals (mean age, 59 years at baseline), the incidence of hypertension, which affected 41% of participants during the nine year follow-up period, was not higher in those with serum 25-hydroxyvitamin D concentrations lower than 20 ng/mL and was only marginally associated with elevated PTH concentrations (192). Nevertheless, a meta-analysis of seven prospective studies, including a total of 48,633 participants with nearly 5,000 incident hypertension cases, found a 30% lower risk of hypertension in those in the top versus bottom tertiles of serum 25-hydroxyvitamin D concentrations. The dose-response analysis estimated that every 10 ng/mL increase in serum 25-hydroxyvitamin D concentration was associated with a 12% lower risk of hypertension (193). Another meta-analysis of four prospective and 14 cross-sectional studies also reported an inverse relationship between circulating 25-hydroxyvitamin D and hypertension (194).

Endothelial dysfunction

Vascular endothelium dysfunction, which contributes to an increased risk of cardiovascular disease (CVD), is common in patients with chronic kidney disease (CKD) (195). In CKD patients, abnormal endothelial function is associated with low values of flow-mediated dilation (FMD) of the brachial artery, a surrogate marker of vascular health. In a recent study conducted in subjects with mild-to-moderate CKD, serum 25-hydroxyvitamin D concentrations were positively associated with FMD values, suggesting a link between suboptimal vitamin D status and endothelial dysfunction (196). In a preliminary intervention study, 26 patients with moderate CKD and vitamin D insufficiency (mean value, 17.2 ng/mL) were supplemented twice with 300,000 IU of vitamin D_3 (at weeks 1 and 8) and followed for a total of 16 weeks. Vitamin D supplementation nearly doubled serum 25-hydroxyvitamin D concentrations and decreased PTH concentrations by 68.5%; improved vitamin D status was accompanied by increased FMD values and reduced levels of endothelial dysfunction markers (197). A recent meta-analysis of 12 small randomized controlled trials in participants at high risk for CVD found a significant increase in FMD with vitamin D supplementation (daily doses, 2,500-5,000 IU; weekly dose, 50,000 IU; monthly dose, 60,000 IU; single-bolus doses, 100,000-200,000 IU) for eight weeks to six months (198).

Cardiovascular events in observational studies and clinical trials

To date, the many epidemiological studies investigating the relationship between vitamin D and outcomes of CVD have provided mixed results (reviewed in 199). Recent Mendelian randomization studies found no association between genetically low serum 25-hydroxyvitamin D concentrations and risks of coronary heart disease, ischemic heart disease, or myocardial infarction (200, 201), suggesting that associations reported in observational studies may be due to confounding or reverse causation. In the RECORD trial in 5,292 older people (see Osteoporosis), supplementation with 800 IU/day of vitamin D_3 (± calcium) reduced the risk of first cardiac failure but had no effect on the risk of myocardial infarction and stroke compared to supplementation with calcium alone or placebo (202). Data on the effect of vitamin D supplementation on cardiovascular events were collected from 21 randomized controlled studies (including the RECORD trial) in 13,033 participants (≥60 years old) and combined in a meta-analysis (202). No effect of vitamin D (including vitamin D analogs) was found for major cardiovascular events, including heart failure, myocardial infarction, and stroke over follow-up periods of 1 to 6.2 years (202). However, caution is advised when interpreting these results since the trials were initially designed to evaluate the effect of vitamin D on bone health, and cardiovascular outcomes were not primary endpoints. Several randomized controlled trials exploring the effect of vitamin D supplementation on CVD risk are currently underway (203), including two large trials, the Vitamin D and Omega-3 Trial (VITAL) in the US (204) and the D-Health trial in Australia (205). The results of one randomized controlled trial, the Vitamin D Assessment (ViDA) trial in New Zealand, were recently published. The total number of CVD events and time to first CVD event during follow-up did not differ between those supplemented with vitamin D_3 (initial dose of 200,000 IU for the first month followed by monthly doses of 100,000 IU) and those given a placebo for a median 3.3 years (206).

Type 2 diabetes mellitus

People with metabolic syndrome are at increased risk for type 2 diabetes mellitus (noninsulin-dependent diabetes mellitus) and cardiovascular disease (CVD). Metabolic syndrome refers to several metabolic disorders, including dyslipidemia, hypertension, insulin resistance, and obesity. A recent study found that the prevalence of type 2 diabetes was associated with low levels of serum 25-hydroxyvitamin D (<30 ng/mL) in 1,801 patients with metabolic syndrome. During an eight-year follow-up period, lower risks of all-cause mortality (72% lower risk) and CVD-specific mortality (64% lower risk) were reported in individuals with serum 25-hydroxyvitamin D concentrations over 30 ng/mL (75 nmol/L) when compared to those with concentrations below 10 ng/mL (25 nmol/L) (207).

In healthy people, vitamin D sufficiency is positively correlated with insulin sensitivity and adequate pancreatic β-cell function. Conversely, vitamin D deficiency might affect glucose homeostasis and cause impaired glucose tolerance and insulin resistance (208). In a cross-sectional study conducted in 12,719 adults, of whom 4,057 had prediabetes (i.e., an increased risk of developing type 2 diabetes), the prevalence of prediabetes was associated with lower concentrations of serum 25-hydroxyvitamin D (≤32.4 ng/mL). Subjects with the lowest concentrations of serum 25-hydroxyvitamin D (≤17.7 ng/mL) were more likely to be current smokers, obese, and have hypertension (209). Vitamin D insufficiency in high-risk individuals may accelerate the progression to overt diabetes. In a prospective study of 2,378 middle-aged men and women followed for 8 to 10 years, the risk for progression to type 2 diabetes from prediabetes was 62% lower in women and 60% lower in men in the highest compared to the lowest quartile of circulating vitamin D (>28.4 ng/mL vs. <18.5 ng/mL). A dose-response analysis measured an average 23% reduction in the risk of progression to type 2 diabetes for every 4 ng/mL (10 nmol/L) increment in serum 25-hydroxyvitamin D concentration (210). A recent review and meta-analysis of 18 prospective cohort studies, including over 210,000 participants followed for a median period of 10 years, found that individuals in the top third of vitamin D levels (reported as either circulating vitamin D or dietary intakes) had lower risks of developing type 2 diabetes (19% lower risk) and metabolic syndrome (14% lower risk) compared to those in the bottom third (211). In another meta-analysis of nine prospective studies, including 28,258 older people (mean age, 67.7 years), lower versus higher circulating vitamin D concentrations at baseline were found to be associated with a 17% higher risk of developing type 2 diabetes over a median follow-up period of 7.3 years (212). Currently, limited evidence suggests that vitamin D supplementation may improve insulin sensitivity in individuals with glucose intolerance or manifest type 2 diabetes (213-216). There is a need for well-designed clinical trials to examine whether maintaining adequate vitamin D levels can prevent adverse metabolic outcomes in healthy and at-risk individuals.

Neurodegenerative diseases

Cognitive impairment and Alzheimer's disease

Alzheimer's disease (AD) is the most common form of dementia, characterized by the presence of extra-neuronal β-amyloid plaques and intra-neuronal Tau protein aggregates (known as neurofibrillary tangles) in the brain. Mechanistic models currently investigated in animal research suggest that vitamin D deficiency or disorders of vitamin D metabolism and/or the disruption of the vitamin D-VDR pathway in the cerebral regions of the cortex and hippocampus may be involved in the degeneration of neurons and loss of cognitive functions (217). Experimental evidence supporting a role for vitamin D in calcium channel regulation, neuroprotection, and immunomodulation in the central nervous system also implies that low vitamin D status may precede or contribute to cognitive dysfunction with age (218).

A number of observational studies have examined cognitive decline and degenerative brain disease in the elderly in relation to dietary intake of vitamin D and serum 25-hydroxyvitamin D concentration. In a large French cohort study on osteoporosis and hip fractures in postmenopausal women, impairments in global cognitive performance, assessed with the Pfeiffer Short Portable Mental State Questionnaire (SPMSQ), were associated with lower dietary intakes of vitamin D (<1,400 IU/week vs. ≥1,400 IU/week) in 5,596 elderly women (mean age, 80.5 years) (219). A seven-year follow-up study of a subgroup of 498 women indicated that the risk of Alzheimer's disease (but not other types of dementia) was 77% lower in those in the highest versus the lowest quintiles of vitamin D dietary intakes at baseline (220). Some, but not all, observational studies have found an association between low serum 25-hydroxyvitamin D concentrations and mild cognitive impairment in older adults (219, 221, 222). The cross-sectional and longitudinal analysis of two prospective studies, which included 1,604 men (223) and 6,257 women (224) aged 65 and over, reported a 60% greater odds of cognitive impairment at baseline and a 58% increased risk of cognitive decline during a four-year follow-up period in women, but not in men, with vitamin D deficiency (circulating 25-hydroxyvitamin D <10 ng/mL vs. ≥30 ng/mL). In the nested case-control, multiethnic, Singapore Kidney Eye Study, which included 2,273 individuals (mean age, 70.4 years), serum 25-hydroxyvitamin D concentrations were inversely correlated with cognitive deficits affecting retrograde episodic memory, semantic memory, and orientation in time, as assessed by the Abbreviated Mental Test (AMT) (225).

Yet, systematic reviews and meta-analyses of observational studies have given mixed results regarding the association of vitamin D status with cognitive performance and AD (226-230). Moreover, the recent analysis of data from 1,182 men followed for 18 years in the Uppsala Longitudinal Study of Adult Men (ULSAM) failed to find associations of genetic determinants of vitamin D synthesis, vitamin D intakes, and plasma 25-hydroxyvitamin D concentrations with risks of cognitive impairments, AD, vascular dementia, or all-cause dementia (231). In contrast, another Mendelian randomization study associated genetic determinants of low vitamin D status to higher risk of AD in the International Genomics of Alzheimer's Project dataset (17,008 AD cases and 37,154 healthy cases) (232).

Nevertheless, the prevalence of vitamin D insufficiency/deficiency ranges between 70% and 90% in older adults, and correcting low concentrations of serum 25-hydroxyvitamin D may help improve cognitive processes, in particular executive functions (233). In a small, non-randomized controlled study in an outpatient clinic, global cognitive function was assessed at baseline and after 16 months in 20 patients supplemented with 800 IU/day (or 100,000 IU/month) of vitamin D and in 24 control subjects. The supplementation of outpatients with vitamin D resulted in the correction of low vitamin D status (average serum 25-hydroxyvitamin D concentration was 16.8 ng/mL at baseline and 30 ng/mL at 16 months) and was associated with a significantly improved scoring in cognition tests compared to the non-supplemented group (234). In a small randomized, placebo-controlled clinical trial in 32 mild-to-moderate AD patients receiving nasal insulin, high doses of vitamin D_2 supplementation for eight weeks (up to 36,000 IU/day) did not significantly improve cognitive performance compared to low doses (1,000 IU/day) (235). More research is needed to investigate a causal relationship between vitamin D repletion and potential long-term cognitive benefits in older adults. Further, it is of great importance to evaluate whether correcting vitamin D deficiency in cognitively impaired subjects can improve the impact of anti-dementia therapy (236).

Parkinson's disease

Parkinson's disease (PD) has been associated with a high prevalence of vitamin D insufficiency among patients, especially those with greater mobility problems (237). A case-control study of 296 outpatients with a mean age of 65 years indicated that 23% of PD subjects had serum 25-hydroxyvitamin D concentrations lower than 20 ng/mL compared to 16% and 10% of AD and healthy individuals, respectively (238). In a prospective cohort study conducted among 3,173 men and women aged 50-79 years and free of PD at baseline, individuals in the highest quartile of serum 25-hydroxyvitamin D (≥20 ng/mL for women and ≥22.8 ng/mL for men) had a 67% lower risk of PD compared to those in the lowest quartile (≤10 ng/mL for women and ≤11.2 ng/mL for men) (239). Meta-analyses pooling data from observational studies all showed that vitamin D inadequacy was more likely reported in subjects with PD than in healthy controls (240-242).

In a randomized, double-blind, placebo-controlled study, 112 PD patients (mean age, 72 years) on standard PD treatment were supplemented with 1,200 IU/day of vitamin D or a placebo for 12 months. Vitamin D supplementation nearly doubled serum 25-hydroxyvitamin D concentration (from mean of 22.5 ng/mL to 41.7 ng/mL) in supplemented subjects and limited the progression of PD, as indicated by a greater proportion of patients who showed no worsening (as assessed by the Hoehn and Yahr stage and the United Parkinson Disease Rating Scale part II) in the supplemented group compared to the placebo group (243). It is not known whether vitamin D insufficiency has a role in the pathogenesis of the disease, but the repletion of vitamin D may provide health benefits that go beyond the prevention and/or the treatment of PD. For example, vitamin D deficiency may contribute to the increased risk of osteoporosis and bone fracture in individuals with neurologic disorders, including PD and multiple sclerosis (244-246). Interestingly, sunlight exposure was found to be associated with improved vitamin D status, higher bone mineral density of the second metacarpal bone, and lower incidence of hip fracture in a prospective study conducted in 324 elderly people with PD (247).

Adverse pregnancy outcomes

A systematic review and meta-analysis of 31 observational studies on maternal vitamin D status and pregnancy outcomes indicated that vitamin D insufficiency may be associated with gestational diabetes mellitus, preeclampsia, and bacterial vaginosis in pregnant women. Low maternal serum vitamin D during pregnancy was also linked to an increased risk for small-for-gestational age infants and low-birth-weight infants, but not for Cesarean section (248). However, the number of intervention trials is currently too limited to draw conclusions as to whether vitamin D supplementation during pregnancy might reduce the incidence of the above-mentioned adverse outcomes (249).

Gestational diabetes mellitus

Abnormal hyperglycemia due to pancreatic β-cell dysfunction characterizes the onset of gestational diabetes mellitus (GDM) in pregnant women without known type 2 diabetes mellitus. This condition is associated with serious adverse maternal outcomes, including preeclampsia, high risk of Cesarean delivery, and life-long increased risk of developing metabolic syndrome and type 2 diabetes mellitus. GDM may also contribute to increased risks of fetal macrosomia (excessive birth weight), neonatal hypoglycemia, infant respiratory distress, and increased life-long risk for obesity, glucose intolerance, type 2 diabetes mellitus, and cardiovascular disease in the offspring (reviewed in 250).

A recent prospective study conducted in 655 pregnant women found that the mean serum 25-hydroxyvitamin D concentration during the first trimester of pregnancy was significantly lower in 54 women who developed incident GDM compared to the rest of the cohort (23 ng/mL vs. 25.4 ng/mL). After multiple adjustments for confounding factors of vitamin D status and GDM risk (including overweight/obesity and prior history of type 2 diabetes and GDM), the study found each 7.5 ng/mL decrease in serum 25-hydroxyvitamin D concentration during early pregnancy was associated with a 48% higher risk of developing GDM (251). Low serum 25-hydroxyvitamin D concentrations (<29.4 ng/mL) during the second trimester of pregnancy were also associated with GDM incidence in a nested case-control study of 118 women with GDM and 219 matched control subjects (252). Five meta-analyses (248, 253-256), including observational studies of moderate-to-high quality, also reported that maternal serum vitamin D concentrations during pregnancy were inversely related to the risk of developing GDM despite evidence of bias amongst studies, such as the use of different methods for serum 25-hydroxyvitamin D measurement, measures done in different trimesters, and different criteria to assess GDM (reviewed in 257).

Further, evidence for the role of vitamin D in glucose regulation during pregnancy was reported in a small randomized, double-blind, placebo-controlled trial in 54 pregnant women diagnosed with GDM. The supplementation with 50,000 IU of vitamin D_3 twice during a six-week period (at day 1 and day 21) resulted in significantly lower fasting plasma glucose and serum insulin concentration, reduced insulin resistance, and improved insulin sensitivity compared to placebo (258). This suggests that vitamin D deficiency may adversely affect glucose tolerance during pregnancy and contribute to the onset of GDM. Yet, the potential benefits of vitamin D supplementation in the prevention of glucose intolerance and GDM during pregnancy have not been assessed. A multicentered, randomized controlled trial (DALI) is ongoing in Europe to evaluate the effects of vitamin D and lifestyle interventions (healthy eating and physical activity) on the metabolic status of pregnant women at risk of GDM (inclusion criteria: pre-pregnancy BMI ≥29 kg/m^2) (259). Preliminary findings suggest that healthy eating and physical activity can help lower gestational weight gain, when compared to standard-of-care; however, these lifestyle changes are unlikely to reduce the risk of GDM among obese pregnant women (260). The results regarding the effect of vitamin D supplementation in the DALI study are yet to be published.

Health outcomes in offspring

During pregnancy, increased intestinal calcium absorption and mobilization of calcium from the skeleton allows accretion of calcium within the fetal skeleton. Yet, observational studies that examined the relationship between maternal vitamin D status and measures of fetal bone growth have not provided consistent results (261, 262). In addition, recent data from the Maternal Vitamin D Osteoporosis Study (MAVIDOS) suggested no difference in whole-body bone mineral content (BMC) of newborns from mothers randomized to daily supplementation with either vitamin D_3 (1,000 IU) or placebo from <17 weeks' gestation until delivery (263). Further, the risk of fracture in Danish children ages 10 to 18 years was similar regardless of whether their mothers were exposed to extra vitamin D from fortification during pregnancy (264). While maternal vitamin D supplementation during pregnancy effectively prevents the neonate's risk of vitamin D deficiency at birth (265), there is little evidence that neonatal vitamin D status influences the risk of fracture later during childhood (266).

A few observational studies have given rather weak evidence in support of a relationship between maternal vitamin D sufficiency during pregnancy and incidence of respiratory conditions and allergies in children (267). A randomized controlled trial found that the supplementation of 108 pregnant women in the third trimester (at week 27 of gestation until delivery) with either 800 IU/day or a bolus dose of 200,000 IU of vitamin D_3 did not decrease the risk of wheezing, allergic rhinitis, food allergy diagnosis, lower respiratory tract infections, or eczema in offspring at three years of age compared to placebo (N=50) (268). A more recent double-blind, randomized controlled trial found that vitamin D_3 supplementation of 295 Danish pregnant women, from weeks 22 to 26 of gestation until delivery, with 2,800 IU/day (70 μg/day) — compared to 400 IU/day (10 μg/day) of vitamin D_3 (i.e., the current recommendation in Denmark) (N=286) — reduced the risk of troublesome episodes of lung symptoms by 17% in offspring during the first three years of life (269). However, no differences were reported regarding the risk of persistent wheeze, asthma, allergic sensitization, respiratory tract infections, or eczema between treatment and control groups (269). In a similar randomized, double-blind, controlled trial — the Vitamin D Antenatal Asthma Reduction Trial — conducted in 777 US pregnant women with a history of asthma, allergic rhinitis, or eczema (or whose partner had such an history), supplementation with 2,400 IU/day (60 μg/day) or 400 IU/day (10 μg/day) did not result in differences in the risk of developing asthma or recurrent wheezing in their children at age three years (270). Despite the lack of significance reported in individual studies, the pooled analysis of the three trials found a 19% reduction in the risk of recurrent wheeze in children whose mothers received high-dose versus low-dose vitamin D supplementation during pregnancy (271). In a cohort of 378 mother-child pairs, high serum 25-hydroxyvitamin D concentrations measured in the 34th week of pregnancy were associated with an increase in food allergy of the child during the first two years of life, warranting careful evaluation of the safety of vitamin D supplementation during pregnancy (272).

Since vitamin D insufficiency has been linked to autoimmunity (see Autoimmune diseases), it has also been proposed that poor maternal vitamin D status during pregnancy may contribute to an increased risk of autoimmune diabetes (insulin-dependent type 1 diabetes mellitus) in the offspring. Yet, the results of a study of 3,723 children at high genetic risk for type 1 diabetes and followed for a mean 4.3 year-period found that maternal intake of vitamin D (from food and/or supplements) during the third trimester of pregnancy (assessed through food frequency questionnaires) was not associated with advanced β-cell autoimmunity or clinical diabetes (142). In a nested case-control study, there was no difference in mean serum concentration of 25-hydroxyvitamin D during the first trimester of pregnancy between 343 mothers of children with type 1 diabetes and 343 control mothers (143). A follow-up study suggested that specific maternal *VDR* polymorphisms, rather than vitamin D status, may be linked to an increased susceptibility to developing type 1 diabetes in children (273). Another nested case-control study (119 mothers of children with type 1 diabetes and 129 control mothers) found an inverse association between maternal vitamin D-binding protein — but not 25-hydroxyvitamin D — concentration during the third trimester of pregnancy and the risk of type 1 diabetes in children (274). At present, there is no established causality between maternal vitamin D status during pregnancy and risk of autoimmune disease in offspring.

Acute respiratory infections

More than 200 viruses are responsible for causing familiar infections of the upper respiratory tract (URT), known as the common cold, resulting in symptoms of nasal congestion and discharge, cough, sore throat, and sneezing (275). The analysis of cross-sectional data from 18,883 participants (ages 12 years and older) of the Third US National Health and Nutrition Examination Survey (NHANES III) reported an inverse relationship between serum 25-hydroxyvitamin D concentrations and recent (self-reported) URT infection (URTI). Compared to levels of circulating vitamin D of 30 ng/mL or above, the risk of URTI was 24% higher in individuals with concentrations between 10 and 29 ng/mL and 36% higher in those with levels below 10 ng/mL (276). A subgroup analysis indicated that low concentrations of serum 25-hydroxyvitamin D in subjects with asthma and chronic obstructive pulmonary disease (COPD) were linked to a greater susceptibility to URTI when compared to people without pulmonary disease.

In a randomized, double-blind, placebo-controlled trial conducted in 322 healthy adults (ages ≥18 years), supplementation with monthly doses of vitamin D_3 (200,000 IU for the first two months and 100,000 IU for the following 16 months) significantly raised the mean serum 25-hydroxyvitamin D concentration (from 29 ng/mL to 48 ng/mL) in the intervention group but did not decrease the occurrence of URTI compared to placebo (277). Moreover, in a larger, multicenter, four-arm clinical trial in 2,259 subjects (aged 45-75 years) with a history of colorectal adenoma, daily vitamin D_3 supplementation of 1,000 IU did not reduce the number or the duration of URTI episodes during winter or the rest of the year, even among participants with the lowest serum 25-hydroxyvitamin D concentrations at baseline (278). In addition, the post-hoc analysis of data from a randomized, placebo-controlled trial in 644 individuals (ages 60-84 years) found that monthly supplementation with 30,000 IU or 60,000 IU of vitamin D_3 for a maximum period of one year did not significantly decrease the rate of antibiotic prescriptions for bacterial airway infections. The stratified analysis, however, found that doses of 60,000 IU/month reduced the risk of using antibiotics in participants ≥70 years old by 47% (279). In addition, compared to placebo, the supplementation of pregnant women with vitamin D_3 (with 2,000 IU/day) for three months until birth followed by the supplementation of their infants (800 IU/day) from birth to six months of age significantly reduced the number of acute respiratory infections after the intervention period in children 6 to 18 months old (280). Interestingly, despite significant heterogeneity among trials, the pooled analysis of these data with that of 21 additional trials suggested an overall 12% reduction in incidence of URTI with vitamin D_3 given as bolus doses (every week, month, or every three months), daily doses, or a combination of bolus and daily doses (281). Subgroup analyses revealed a 42% reduction in URTI risk with vitamin D_3 supplementation in subjects with baseline serum 25-hydroxyvitamin D concentrations <10 ng/mL, while there was no protective effect of vitamin D_3 in those with concentrations ≥10 ng/mL. Moreover, large bolus doses (≥30,000 IU) were found to be ineffective compared to daily or weekly doses such that, in subgroup analyses that excluded bolus doses, daily and weekly vitamin D_3 regimens appeared to be protective against URTI regardless of baseline vitamin D status. Finally, the effect of vitamin D_3 supplementation on URTI did not appear to vary with age, BMI, the presence of asthma or COPD, and flu vaccination status (281).

The findings of a large clinical trial in New Zealand, the Vitamin D Assessment (ViDA) Study, confirmed the ineffectiveness of large bolus doses of vitamin D in reducing the risk of acute respiratory infections (282). In this double-blind, placebo-controlled trial in 5,110 older adults (ages 50-84 at baseline), supplementation with an initial dose of 200,000 IU of vitamin D_3 followed by 100,000 IU/month of vitamin D_3 for a median of 3.3 years had no effect on the incidence of (self-reported) acute respiratory infections (HR, 1.01; 95% CI, 0.94-1.07). Upon data stratification by vitamin D status, a similar null result (HR, 1.08; 95% CI, 0.95-1.23) was seen in study participants with blood vitamin D concentrations ≤20 ng/mL (≤50 nmol/L; 282).

The recently completed VITAL (Vitamin D and Omega-3 Trial) may provide additional evidence of an effect of daily dosing (2,000 IU/day of vitamin D) on risk of airway infections in older adults, although the prevention of infectious disease is a secondary outcome in the trial (204, 283, 284).

In a trial in preschool-age children, vitamin D supplementation with 2,000 IU/day for at least four months did not decrease the incidence (285) or severity (286) of URTI in winter compared to supplementation with 400 IU/day for at least four months. Supplementation with 2,000 IU/day led to significantly higher mean serum 25-hydroxyvitamin D concentrations compared to the lower dose (48.7 ng/mL vs. 36.8 ng/mL), but the 400 IU dose may have been sufficient to prevent URTI in these young children (285). In a placebo-controlled trial in 1,300 healthy children and adolescents in rural Vietnam (baseline 25-hydroxyvitamin D concentrations of 26 ng/mL for both the control and intervention group), supplementation with 14,000 IU/week of vitamin D for eight months significantly reduced the incidence of non-influenza viral respiratory infections by 24%, but not the incidence of influenza A or B infection (287).

Coronavirus disease, COVID-19

The coronavirus disease, COVID-19, is caused by infection with the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2). This virus originated in Wuhan, China in late 2019 and rapidly spread throughout the world causing a global pandemic. Flu-like symptoms, including cough, fever, fatigue, and difficulty breathing, as well as several other diverse symptoms characterize COVID-19 (see the websites of the CDC and the WHO). The effects of the disease vary widely, with the most severe resulting in pneumonia, respiratory distress, and death. Some individuals infected with SARS-CoV-2, however, are asymptomatic but can transmit virus to others (288). Moreover, SARS-CoV-2 infected individuals can spread disease before they experience symptoms (i.e., presymptomatic transmission) (289), placing importance on public health measures like hand washing, face mask wearing, social distancing, and testing and contact tracing to curtail the pandemic.

A number of observational studies have examined the correlation of vitamin D status and COVID-19 incidence, with most — but not all (290-292) — finding vitamin D deficiency or insufficiency associated with an increased risk of SARS-CoV-2 infection. In a retrospective cohort study of more than 191,000 US residents administered a SARS-CoV-2 test during a three-month period in spring 2020, SARS-CoV-2 positivity was strongly associated with a lower serum 25-hydroxyvitamin D concentration, measured at a single point in the 12 months prior to the viral test (293). In this study, each 1 ng/mL increment of serum 25-hydroxyvitamin D was linked to a 1.6% lower risk of SARS-CoV-2 positivity, with the risk being the lowest at serum concentrations of 55 ng/mL and above (293). In a retrospective, population-based study among 7,807 people in Israel, including 782 SARS-CoV-2 positive cases, plasma 25-hydroxyvitamin D concentrations below 30 ng/mL were associated with a 50% higher risk of SARS-CoV-2 infection compared to higher vitamin D concentrations (294). The vitamin D status assessment in this study was done prior to the viral testing, but details on the time frame are lacking. The temporal relationship of the vitamin D status measure and COVID diagnostic test is also a concern in an analysis of a large dataset from the UK Biobank, which found vitamin D status was not associated with SARS-CoV-2 infection: the study utilized vitamin D status assessments done 10 to 14 years prior to the COVID-19 diagnostic test (291). Consistent with findings of most available studies, a small retrospective cohort study (295) and five case-control studies (296-300) reported an inverse association of vitamin D status and SARS-CoV-2 infection. A 2021 meta-analysis of 10 observational studies, including 361,934 participants, reported an association between vitamin D insufficiency or deficiency and increased risk of COVID-19 (OR, 1.43; 95% CI: 1.00-2.05), although heterogeneity across studies was high (301). Further, in an analysis of data from the UK Biobank, regular use of vitamin D supplements was found to be associated with a 34% lower risk of SARS-CoV-2 infection compared nonusers of vitamin D supplements (292).

Additionally, most of the available observational research suggests an association between low vitamin D status and COVID-19 severity, with studies finding vitamin D deficiency linked to an increased risk of disease severity, as measured by need for hospitalization, intensive care unit admission (302), stage of pneumonia (in men but not in women; 303), need for non-invasive ventilation (304), need for invasive mechanical ventilation (305), or a combination of these and other indicators (297). Another study found that insufficient vitamin D status, defined as plasma 25-hydroxyvitamin D concentrations below 30 ng/mL, was associated with an increased likelihood of COVID-related hospitalization, but the association failed to reach statistical significance ($p=0.061$) except in a subanalysis of individuals over 50 years of age (OR, 2.71; 95% CI: 1.55-4.78; $p<0.001$) (294). In contrast to most of the evidence to date, one case-control study found vitamin D deficiency was not linked to COVID-19 severity (298). Further, a few studies have looked at the relationship of vitamin D status and COVID-19 mortality, with three finding vitamin D deficiency to be associated with an increased risk of death (303, 305, 306) and two finding no association (304, 307), although one of the studies finding no association used vitamin D status measurements more than 10 years prior to the COVID-19 diagnostic testing (307).

Since there are several known risk factors for severe illness from COVID-19, including advanced age, obesity, and preexisting type 2 diabetes or cardiovascular disease (308), it is important for observational studies to control for potential confounders. Two quasi-experimental studies reported that bolus supplementation with vitamin D_3 (either 50,000 IU per month or 80,000-100,000 IU every two to three months) prior to or during SARS-CoV-2 infection was associated with a less severe illness and improved survival in frail elderly COVID-19 patients (309, 310). A number of randomized controlled trials of vitamin D supplementation in COVID-19 prevention and treatment are currently underway; the results of these trials will inform on the causality of the association. Nevertheless, the currently available data indicate that improving vitamin D status through supplementation represents a modifiable risk factor for COVID-19.

Disease Treatment

Atopic dermatitis

Atopic dermatitis or eczema is particularly prevalent in industrialized countries, affecting 10%-20% of children and 1%-3% of adults. Atopic dermatitis is a chronic inflammatory skin disorder characterized by dry and pruritus (itchy) areas of the skin in affected subjects. Local skin inflammation and immune dysfunction can damage the epidermal barrier and increase the susceptibility to skin infections and atopic reactions in affected individuals. The disease is often associated with other atopic diseases, including food allergies, asthma, and allergic rhinitis (311).

While the etiology of the disease is not fully elucidated, it has been suggested that vitamin D deficiency might contribute to the onset and/or the severity of the disease (312). Recently, using large-scale datasets from Caucasian people of European descent, including the UK Biobank resource (313) and the SUNLIGHT (35), the GABRIEL asthma (314), and EAGLE eczema (315) consortia, a Mendelian randomization study found no association between genetically low serum 25-hydroxyvitamin D concentrations and risks of atopic dermatitis, asthma, or high serum immunoglobulin (Ig)-E concentrations (316).

A number of randomized controlled studies have examined whether vitamin D might be an effective adjunct tool in disease management, possibly through regulating local inflammatory reactions and stimulating antimicrobial activities in the skin. Moreover, the beneficial effect of phototherapy observed in specific cases of atopic dermatitis may be partly mediated by the action of vitamin D (311). In a small randomized, double-blind, placebo-controlled study in 45 patients with atopic dermatitis and low vitamin D status (70% of subjects had serum 25-hydroxyvitamin D concentrations <20 ng/mL), daily administration of 1,600 IU of oral vitamin D_3, alone or together with 600 IU/day of vitamin E, for a period of 60 days significantly reduced the extent and intensity of eczema, as assessed by the SCORAD (SCORing Atopic Dermatitis) score (317). Vitamin D_3 (1,600 IU/day for 60 days) also improved vitamin D status and reduced disease severity in 53 patients with atopic dermatitis in another small randomized trial (318). More recently, vitamin D_3 (1,000 IU/day for one month) improved the severity of winter-related atopic dermatitis in Mongolian children, as shown by changes in Eczema Area and Severity Index (EASI) and Investigator's Global Assessment (IGA) scores (319). A meta-analysis of four small trials (including those cited above) confirmed that supplemental vitamin D can lead to measurable clinical improvements in affected individuals (320). Larger trials are needed to strengthen these preliminary findings and determine the most appropriate and effective supplementation regimen. Of note, topical treatment of psoriasis with vitamin D analogs has been approved by the US Food and Drug Administration (FDA) and may be effective in the management of other skin disorders (321).

Inflammatory bowel diseases

Several ill-defined environmental and genetic factors are thought to contribute to the development of the inappropriate immune response to the intestinal microbiota that causes ulcerative colitis (UC) and Crohn's disease (CD). While specific *VDR* polymorphisms may be linked to an increased susceptibility to developing UC and CD (322), higher vitamin D intakes and predicted circulating levels were found to be associated with a reduced incidence of UC and CD in a large cohort of 72,719 women (323). A meta-analysis of six observational studies found an inverse association between vitamin D status and severity of CD (324). Three studies have investigated whether vitamin D_3 could benefit patients with CD, possibly through reducing intestinal inflammation. In one multicenter, double-blind, placebo-controlled study, the relapse rate in CD patients in remission after one year of treatment was significantly lower in those supplemented daily with 1,200 IU of vitamin D_3 and 1,200 mg of calcium compared to those who received calcium alone (13% vs. 29%) (325). In a second pilot study, incremental daily doses of vitamin D_3, from 1,000 IU up to 5,000 IU, were administrated over a 24-week period to 18 CD patients in order to achieve circulating 25-hydroxyvitamin D concentrations >40 ng/mL. Although half of the patients failed to achieve 40 ng/mL, the mean 25-hydroxyvitamin D concentration was raised to 45 ng/mL (from a baseline mean of 16 ng/mL), and the overall improvement in vitamin D status was associated with a significant decrease in disease severity as assessed by Crohn's Disease Activity (CDAI) scores (326). In a three-month, randomized, double-blind, placebo-controlled trial in 27 CD patients in remission, daily supplementation with vitamin D_3 (2,000 IU) improved vitamin D status but had no significant effect on intestinal permeability ('leaky gut') or measures of inflammation and disease activity (327). Yet, the study suggested that achieving serum 25-hydroxyvitamin D concentrations ≥30 ng/mL might help reduce intestinal inflammation and improve patients' quality of life. Additional studies are needed to confirm the therapeutic efficacy of vitamin D in inflammatory bowel diseases.

Cardiovascular disease

The prospective analysis of 41,504 electronic medical records in the Intermountain Heart Collaborative study found that only one-third of patients had adequate serum 25-hydroxyvitamin D concentrations (>30 ng/mL); vitamin D insufficiency (serum 25-hydroxyvitamin D concentrations ≤30 ng/mL) was associated with increased prevalence and incidence of many cardiovascular conditions, including hypertension, coronary artery disease, heart failure, and stroke (328). Suboptimal vitamin D status has also been linked to arterial stiffness and vascular endothelial dysfunction — strong determinants of incident hypertension and adverse cardiovascular outcomes (329).

Hypertension

Several intervention studies have evaluated the effect of vitamin D supplementation on blood pressure. An early controlled clinical trial in 18 men and women with untreated mild hypertension living in the Netherlands found that exposure to UVB radiation three times weekly for six weeks during the winter increased serum 25-hydroxyvitamin D concentrations by 162%, lowered PTH concentrations by 15%, and decreased 24-hour ambulatory systolic and diastolic blood pressure measurements by an average of 6 mm Hg (330). A recent meta-analysis of 16 randomized controlled trials involving 1,879 participants, either healthy or with pre-existing cardiometabolic conditions (including hypertension), found no significant reduction in systolic and diastolic blood pressures with vitamin D supplementation (800-8,571 IU/day for five weeks to one year). However, a subgroup analysis of six trials found a significant reduction of 1.31 mm Hg in diastolic blood pressure in individuals with preexisting conditions. While improvements in blood pressure may be expected in cases of vitamin D insufficiency/deficiency, the authors noted that suboptimal vitamin D status in participants was not exclusively observed in those with cardiometabolic conditions (331). In contrast, in two recent intervention studies — the Styrian vitamin D hypertension trial (332) and the Vitamin D therapy in individuals at high risk of hypertension trial [DAYLIGHT] (333) — subjects with (pre)hypertension supplemented with vitamin D_3 (400 to 4,000 IU/day for two to six months) showed no evidence of blood pressure lowering, regardless of their baseline vitamin D status (insufficient or adequate, according to the IOM's current cutoffs).

Conditions that decrease vitamin D synthesis in the skin, such as having dark-colored skin, living in temperate latitudes, and aging, are associated with increased prevalence of hypertension (334), suggesting that vitamin D may reduce blood pressure levels in selected groups of individuals. In the above-mentioned meta-analysis, one four-arm, double-blind, placebo-controlled clinical trial was conducted in 283 African Americans randomized to receive daily vitamin D_3 supplements of 1,000 IU, 2,000 IU, or 4,000 IU for a period of three months. Systolic blood pressure was decreased by 0.66 mm Hg with 1,000 IU/day, 3.4 mm Hg with 2,000 IU/day, and by 4 mm Hg with 4,000 IU/day while it increased by 1.7 mm Hg in the placebo group when compared to baseline. A significant reduction of 0.2 mm Hg in systolic blood pressure was detected per 1 ng/mL incremental increase in 25-hydroxyvitamin D concentration. However, there was no statistical difference on three-month change in blood pressure between vitamin D_3 and placebo (335). Another randomized, placebo-controlled study in 150 elderly participants (mean age, 77 years) showed that supplementation with 100,000 IU of vitamin D_3 every three months for one year did not significantly lower blood pressure compared to placebo (336).

Further research is needed to determine whether vitamin D supplementation is helpful in the prevention or management of hypertension.

Congestive heart failure

Congestive heart failure (also called cardiac insufficiency) is characterized by increased heart rate and subsequent hypertrophy of the left heart ventricle. Cardiac insufficiency is associated with a reduced left ventricular ejection fraction (LVEF), assessed by echocardiography. Inhibitors of angiotensin-converting enzyme (ACE) (see Blood pressure regulation) are currently used as first-line therapy for patients with heart failure. In a cross-sectional study in healthy patients who underwent coronary angiography, serum 25-hydroxyvitamin D concentrations <30 ng/mL were associated with poorer coronary flow rates (337). Suboptimal vitamin D status has also been linked to poorer prognosis in patients with heart failure (338). Over the past several years, a number of intervention studies have examined the effect of vitamin D supplementation in those with cardiac insufficiency. In a 12-week randomized, double-blind, placebo-controlled study, daily supplementation with 1,200 IU of vitamin D_3 in children with chronic congestive heart failure led to a significant increase in vitamin D status accompanied by an improved heart muscle performance (increased LVEF), as well as by lower levels of PTH and pro-inflammatory cytokines (339). In another randomized, double-blind, placebo-controlled trial in 64 elderly patients with heart failure, participants receiving 800 mg/day of calcium and 50,000 IU/week of vitamin D_3 did not perform significantly better at physical performance tasks (used as proxy to assess aerobic capacity and skeletal muscle strength) compared to those supplemented with calcium only (340). A recent meta-analysis of seven small randomized placebo-controlled trials in 573 subjects with heart failure showed that vitamin D supplementation (from 1,000 IU/day to 50,000 IU/week) for six weeks to nine months could reduce serum concentrations of PTH, tumor necrosis factor-α (TNF-α), and C-reactive protein (CRP). Yet, there were no significant differences in LVEF, circulating interleukin-10 (IL-10) concentration, and renin concentration between patients treated with vitamin D and those given a placebo (341). Finally, in the EVITA (Effect of vitamin D on all-cause mortality) trial in patients with end-stage heart failure and inadequate vitamin D status (baseline serum 25-hydroxyvitamin D values, 8.6-19.7 ng/mL), supplementation with 4,000 IU/day for three years did not reduce the risk of mortality compared to placebo (342).

Sources

Sunlight

Solar ultraviolet-B radiation (UVB; wavelengths of 290 to 315 nanometers) stimulates the production of vitamin D_3 in the epidermis of the skin (343). Sunlight exposure can provide most people with their entire vitamin D requirement. Children and young adults who spend a short time outside two or three times a week will generally synthesize all the vitamin D they need to prevent deficiency. One study reported that serum vitamin D concentrations following exposure to one minimal erythemal dose of simulated sunlight (the amount required to cause a slight pinkness of the skin) to the whole body was equivalent to ingesting approximately 10,000 to 25,000 IU of vitamin D (344). People with dark-colored skin synthesize markedly less vitamin D on exposure to sunlight than those with lighter complexion (34). Additionally, older adults have diminished capacity to synthesize vitamin D from sunlight exposure and frequently use sunscreen or protective clothing in order to prevent skin cancer and sun damage. The application of sunscreen with an SPF factor of 10 reduces production of vitamin D by 90% (30). In latitudes around 40 degrees north or 40 degrees south (Boston is 42 degrees north), there is insufficient UVB radiation available for vitamin D synthesis from November to early March. Ten degrees farther north or south (Edmonton, Canada), the "vitamin D winter" extends from mid-October to mid-March. It has been estimated that up to 15 minutes of daily sun exposure on the hands, arms, and face around 12 pm throughout the year at 25 degrees latitude (Miami, FL) and during the spring, summer, and fall at 42 degrees (Boston, MA) latitude may provide a light-skinned individual with 1,000 IU of vitamin D (345).

Food sources

Vitamin D is found naturally in only a few foods, such as some fatty fish (mackerel, salmon, sardines), fish liver oils, eggs from hens that have been fed vitamin D, and mushrooms exposed to sunlight or UV light. In the US, milk and infant formula are fortified with vitamin D so that they contain 400 IU (10 μg) per quart. However, other dairy products, such as cheese and yogurt, are not always fortified with vitamin D. Some cereal, bread, and fruit juices may also be fortified with vitamin D. Accurate estimates of average dietary intakes of vitamin D are difficult because of the high variability of the vitamin D content of fortified foods (346). The vitamin D content (sum of vitamin D_2 and vitamin D_3) of some vitamin D-rich foods is listed in **Table 2** in both international units (IU) and micrograms (μg). For more information on the nutrient content of specific foods, search USDA's FoodData Central. The 25-hydroxyvitamin D metabolite is also present at low levels is certain foods, including meats, dairy products, and eggs (347, 348).

Table 2. Some Food Sources of Vitamin D

Food	Serving	Vitamin D (IU)	Vitamin D (μg)
Pink salmon, canned	3 ounces	465	11.6
Mackerel, canned (boneless)	3 ounces	248	6.2
Sardines, canned	3 ounces	164	4.1
Milk, low-fat (1%), fortified with vitamin D	8 fluid ounces	108	2.7
Orange juice, fortified with vitamin D	8 fluid ounces	100	2.5
Cereal, fortified	1 serving (usually 1 cup)	40-50	1.0-1.3
Egg yolk	1 large	37	0.9

Supplements

Most vitamin D supplements available without a prescription contain cholecalciferol (vitamin D_3). Multivitamin supplements generally provide 400 IU-1,000 IU (10 μg-25 μg) of vitamin D_2 or vitamin D_3. Single-ingredient vitamin D supplements may provide 400 to 50,000 IU of vitamin D_3, but 400 IU is the most commonly available dose (66). A number of calcium supplements may also provide vitamin D. A meta-analysis of randomized controlled trials suggested that bolus doses of vitamin D_2 (ergocalciferol) may not always be as effective as vitamin D_3 in raising serum 25-hydroxyvitamin D concentrations, yet no difference in efficacy was found with daily supplementation with vitamin D_2 or vitamin D_3 (349). Nonetheless, a 25-week, randomized, double-blind, placebo-controlled trial found daily supplementation with 1,000 IU of vitamin D_3 initiated at the end of summer to be more efficacious than vitamin D_2 in maintaining summertime concentrations of 25-hydroxyvitamin D during fall and winter months (350).

There is growing interest in using the hydroxylated form of cholecalciferol, 25-hydroxyvitamin D_3 (calcidiol; calcifediol), as a supplement. This vitamin D metabolite is synthesized by the liver of humans and animals from cholecalciferol produced in skin or consumed in the diet, and is present in some foods (e.g., meats, milk, eggs) at low levels (347, 348). In general, clinical studies have found calcifediol is two to five times more potent at increasing blood concentrations of 25-hydroxyvitamin D compared to supplementation with equivalent doses of cholecalciferol (351-359). Supplementation with calcifediol may thus represent a means to improve vitamin D status rapidly and consistently with lower doses than cholecalciferol and may benefit those individuals with conditions that decrease intestinal absorption of cholecalciferol (359). However, the 25-hydroxyvitamin D_3 form is presently not available as an over-the-counter supplement in the United States.

Safety

Toxicity

Vitamin D toxicity (hypervitaminosis D) has not been observed to result from sun exposure. The reason is that excessive sunlight exposure generates a number of biologically inert photoproducts from 7-dehydrocholesterol and cholecalciferol (3). Vitamin D toxicity induces abnormally high serum calcium concentration (hypercalcemia), which could result in bone loss, kidney stones, and calcification of organs like the heart and kidneys if untreated over a long period of time. Hypercalcemia has been observed following daily doses of greater than 50,000 IU of vitamin D (360). Overall, research suggests that vitamin D toxicity is very unlikely in healthy people at intake levels lower than 10,000 IU/day (361-363). However, the Food and Nutrition Board of the IOM conservatively set the tolerable upper intake level (UL) at 4,000 IU/day (100 μg/day) for all adults (**Table 3**). Certain medical conditions can increase the risk of hypercalcemia in response to vitamin D, including primary hyperparathyroidism, sarcoidosis, tuberculosis, and lymphoma (361). People with these conditions may develop hypercalcemia in response to any increase in vitamin D nutrition and should consult a qualified health care provider regarding any increase in vitamin D intake.

Table 3. Tolerable Upper Intake Level (UL) for Vitamin D

Age Group	μg/day	IU/day
Infants 0-6 months	25	1,000
Infants 6-12 months	37.5	1,500
Children 1-3 years	62.5	2,500
Children 4-8 years	75	3,000
Children 9-13 years	100	4,000
Adolescents 14-18 years	100	4,000
Adults 19 years and older	100	4,000

Drug interactions

The following medications should not be taken at the same time as vitamin D because they can decrease the intestinal absorption of vitamin D: cholestyramine (Questran), colestipol (Colestid), orlistat (Xenical), and mineral oil (364, 365). The following medications increase the metabolism of vitamin D and may decrease serum 25-hydroxyvitamin D concentrations: phenytoin (Dilantin), fosphenytoin (Cerebyx), phenobarbital (Luminal), carbamazepine (Tegretol), and rifampin (Rimactane) (6). Cimetidine, a H_2 blocker that suppresses stomach acid secretion, inhibits the hydroxylation of vitamin D in the liver (366). Treating acid reflux, gastroesophageal reflux disease (GERD), or ulcers with proton-pump inhibitors (omeprazole, lansoprazole) might interfere with calcium absorption and increase the risk of fracture such that patients are advised to take calcium and vitamin D supplements (367). The oral antifungal medication, ketoconazole, inhibits the 25-hydroxyvitamin D_3-1α-hydroxylase enzyme and has been found to reduce serum 1α,25-dihydroxyvitamin D concentrations in healthy men (368). The Endocrine Society also recommends monitoring vitamin D status of patients on glucocorticoids and HIV treatment drugs because these medications increase the catabolism of 25-hydroxyvitamin D (40). The use of some cytostatic agents (cell growth inhibitors) may also increase the degradation of 25-hydroxyvitamin D and 1α,25-dihydroxyvitamin D in cancer patients under chemotherapy (6). The induction of hypercalcemia by toxic levels of vitamin D may precipitate cardiac arrhythmia in patients on digoxin (Lanoxin) (366). Hypercalcemia may also reduce the effectiveness of verapamil (Calan) and diltiazem (Cardizem) in atrial fibrillation (366).

Linus Pauling Institute Recommendation

The Linus Pauling Institute recommends that generally healthy adults take 2,000 IU (50 μg) of supplemental vitamin D daily. Most multivitamins contain 400 IU (10 μg) of vitamin D, and single-ingredient vitamin D supplements are available for additional supplementation. Sun exposure, diet, skin color, and body mass index (BMI) have variable, substantial impact on body vitamin D levels. To adjust for individual differences and ensure adequate body vitamin D status, the Linus Pauling Institute recommends aiming for a serum 25-hydroxyvitamin D concentration of at least 30 ng/mL (75 nmol/L). Observational studies suggest that serum 25-hydroxyvitamin D concentrations between 30 ng/mL and 60 ng/mL are associated with lower risks of adverse health outcomes, including cancers and autoimmune diseases.

The American Academy of Pediatrics currently suggests that all infants, children, and adolescents receive 400 IU of supplemental vitamin D daily (19). Consistent with the recommendations of the Endocrine Society (40), the Linus Pauling Institute recommends daily intakes of 400 to 1,000 IU (10 to 25 μg) of vitamin D in infants and 600 to 1,000 IU (15 to 25 μg) of vitamin D in children and adolescents. Given the average vitamin D content of breast milk, infant formula, and the diets of children and adolescents, supplementation may be necessary to meet these recommendations.

Older adults (>50 years)

Daily supplementation with 2,000 IU (50 μg) of vitamin D is especially important for older adults because aging is associated with a reduced capacity to synthesize vitamin D in the skin upon sun exposure.

Read the Nutrition Information Brief on vitamin E by Maret G. Traber, Ph.D.

Summary

- Naturally occurring vitamin E includes eight fat-soluble isoforms: α-, β-, γ-, and δ-tocopherol and α-, β-, γ-, and δ-tocotrienol. Yet, the body preferentially uses α-tocopherol, and only α-tocopherol supplementation can reverse vitamin E deficiency symptoms. *(More information)*
- α-Tocopherol functions as a chain-breaking antioxidant, preventing the propagation of free radicals in membranes and plasma lipoproteins. α-Tocopherol is also likely involved in strengthening certain aspects of cell-mediated immunity. *(More information)*
- Vitamin E deficiency can be caused by fat malabsorption disorders or by genetic abnormalities that affect vitamin E transport. Severe deficiency symptoms include vitamin E deficiency-induced ataxia, peripheral neuropathy, muscle weakness, and damage to the retina of the eye. *(More information)*
- The current recommended dietary allowance (RDA) is 15 mg/day of α-tocopherol. It is estimated that more than 90% of Americans adults do not meet the estimated average requirement (EAR) of 12 mg/day of α-tocopherol. *(More information)*
- Randomized controlled trials investigating primary and/or secondary prevention of chronic diseases, such as cardiovascular disease, cancer, and cataracts, do not currently support a preventative effect of supplemental α-tocopherol. *(More information)*
- Limited clinical evidence suggests that vitamin E supplementation may be beneficial for managing age-related macular degeneration and

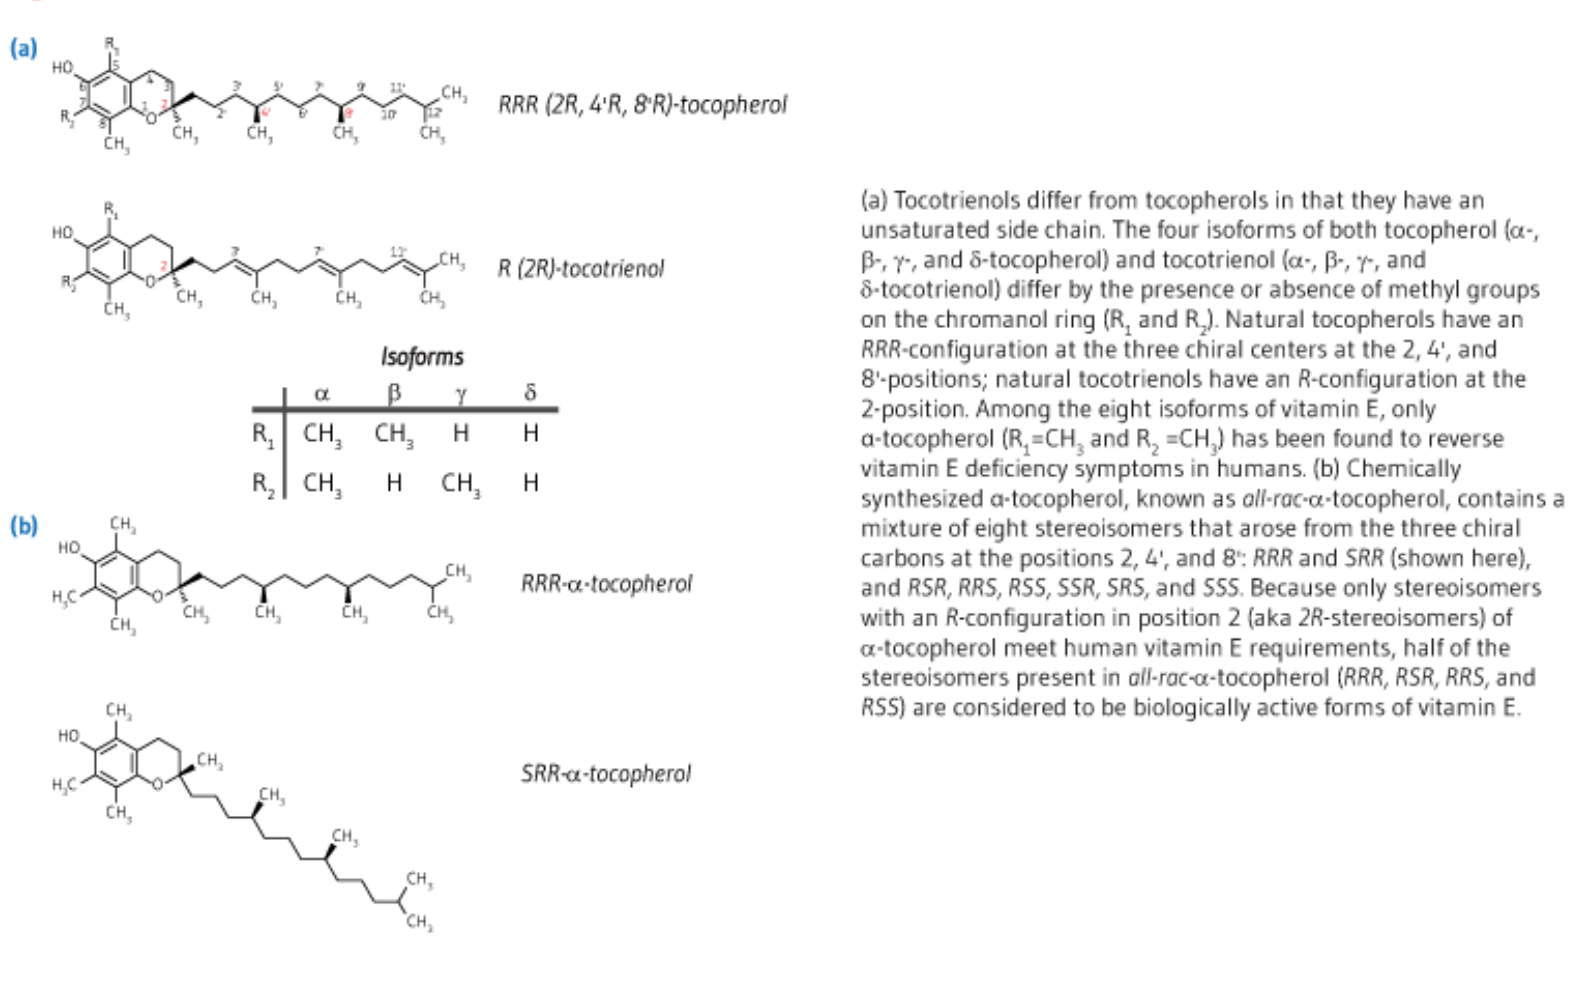
fatty liver diseases secondary to type 2 diabetes mellitus. *(More information)*

- Supplementation with α-tocopherol was found to slow cognitive decline or loss of functional abilities in cognitively impaired subjects in some, but not all, clinical studies. *(More information)*
- Plant seeds, especially sunflower seeds, almonds, and hazelnuts, are rich sources of α-tocopherol such that many vegetable oils (e.g., olive oil and canola oil) also contain α-tocopherol. Other sources include tomato, avocado, spinach, asparagus, Swiss chard, and broccoli. *(More information)*
- High doses of supplemental α-tocopherol may interfere with the vitamin K-dependent blood clotting cascade and increase the risk of bleeding in individuals taking anticoagulant drugs. A tolerable upper intake level (UL) for α-tocopherol in adults is set at 1,000 mg/day and applies to all possible stereoisomers of α-tocopherol. *(More information)*

The term vitamin E describes a family of eight fat-soluble molecules with antioxidant activities: four tocopherol isoforms (α-, β-, γ-, and δ-tocopherol) and four tocotrienol isoforms (α-, β-, γ-, and δ-tocotrienol) (**Figure 1**). Only one form, α-tocopherol, meets human vitamin E requirements (see The RDA). In the human liver, α-tocopherol is the form of vitamin E that is preferentially bound to α-tocopherol transfer protein (α-TTP) and incorporated into lipoproteins that transport α-tocopherol in the blood for delivery to extrahepatic tissues. Therefore, it is the predominant form of vitamin E found in the blood and tissues (1). In addition, α-tocopherol appears to be the form of vitamin E with the greatest nutritional significance, such that it will be the primary topic of the following discussion.

Figure 1. Chemical Structures of Vitamin E Isoforms



(a) Tocotrienols differ from tocopherols in that they have an unsaturated side chain. The four isoforms of both tocopherol (α-, β-, γ-, and δ-tocopherol) and tocotrienol (α-, β-, γ-, and δ-tocotrienol) differ by the presence or absence of methyl groups on the chromanol ring (R_1 and R_2). Natural tocopherols have an *RRR*-configuration at the three chiral centers at the 2, 4', and 8'-positions; natural tocotrienols have an *R*-configuration at the 2-position. Among the eight isoforms of vitamin E, only α-tocopherol (R_1=CH_3 and R_2 =CH_3) has been found to reverse vitamin E deficiency symptoms in humans. (b) Chemically synthesized α-tocopherol, known as *all-rac*-α-tocopherol, contains a mixture of eight stereoisomers that arose from the three chiral carbons at the positions 2, 4', and 8': *RRR* and *SRR* (shown here), and *RSR, RRS, RSS, SSR, SRS*, and *SSS*. Because only stereoisomers with an *R*-configuration in position 2 (aka *2R*-stereoisomers) of α-tocopherol meet human vitamin E requirements, half of the stereoisomers present in *all-rac*-α-tocopherol (*RRR, RSR, RRS*, and *RSS*) are considered to be biologically active forms of vitamin E.

[Figure 1 - Click to Enlarge]

Function

α-Tocopherol

Natural versus synthetic α-tocopherol

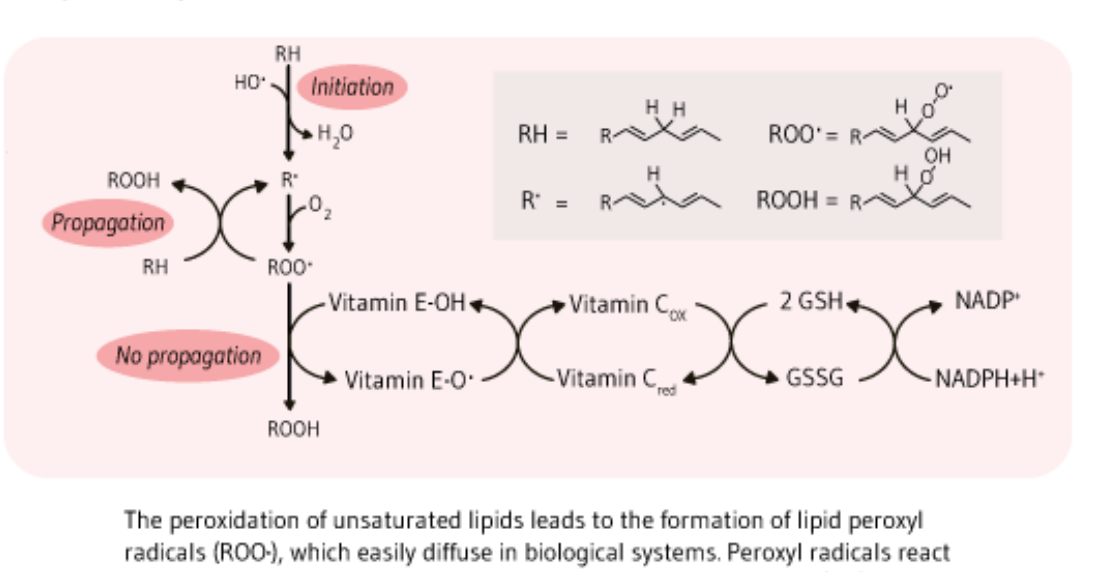
Natural α-tocopherol made by plants found in food has an *RRR*-configuration at the 2, 4', and 8'-position of the α-tocopherol molecule (wrongly referred to as *d*-α-tocopherol) (see **Figure 1**). Chemically synthesized *all-rac*-α-tocopherol (*all-racemic*-α-tocopherol; incorrectly labeled *dl*-α-tocopherol) is a mixture of eight stereoisomers of α-tocopherol, which arose from the three chiral carbons at the 2, 4', and 8'-positions: *RRR*-, *RSR*-, *RRS*-, *RSS*-, *SRR*-, *SSR*-, *SRS*-, and *SSS*-α-tocopherol (see **Figure 1**). While all stereoisomers have equal *in vitro* antioxidant activity, only the forms in the *R*-conformation at position 2 (noted 2*R*) meet the vitamin E requirements in humans (2).

Antioxidant activity

The main function of α-tocopherol in humans is that of a fat-soluble antioxidant. Fats, which are an integral part of all cell membranes, are vulnerable to damage through lipid peroxidation by free radicals. α-Tocopherol is uniquely suited to intercept peroxyl radicals and thus prevent a chain reaction of lipid oxidation (**Figure 2**). When a molecule of α-tocopherol neutralizes a free radical, it is oxidized and its antioxidant capacity is lost. Other antioxidants, such as vitamin C, are capable of regenerating the antioxidant capacity of α-tocopherol (**Figure 2**) (reviewed in 1).

Aside from maintaining the integrity of cell membranes throughout the body, α-tocopherol protects the fats in low-density lipoproteins (LDLs) from oxidation. Lipoproteins are particles composed of lipids and proteins that transport fats through the bloodstream. LDLs specifically transport cholesterol from the liver to the tissues of the body. Oxidized LDLs have been implicated in the development of cardiovascular disease (3).

Figure 2. Antioxidant Activity of α-Tocopherol



The peroxidation of unsaturated lipids leads to the formation of lipid peroxyl radicals (ROO•), which easily diffuse in biological systems. Peroxyl radicals react 1,000 times faster with α-tocopherol than with unsaturated lipids (RH). The hydroxyl group in the chromanol head of α-tocopherol can donate hydrogen to scavenge lipid peroxyl radicals, which halts their propagation in membranes and circulating lipoproteins. The presence of other antioxidants, such as vitamin C (ascorbate), is required to regenerate the antioxidant capacity of α-tocopherol. *GSSH, oxidized glutathione; GSH, reduced glutathione, NADP, nicotinamide adenine diphosphate; NADPH, reduced NADP; RH, unsaturated lipid; R•, lipid (carbon-centered) radical; ROO•,* hydroperoxide; Vitamin E-OH, α-tocopherol (reduced form); *Vitamin E-O•, tocopheroxyl radical (oxidized form); Vitamin* C_{ox}*, dehydroascorbate (oxidized vitamin C); Vitamin* C_{red}*, ascorbate (reduced vitamin C).*

[Figure 2 - Click to Enlarge]

Effects on cell-mediated immunity

Other functions of α-tocopherol are likely to be related to its antioxidant capacity (1). For instance, α-tocopherol can protect the physiological properties of lipid bilayer membranes and may influence the activity of membrane proteins and enzymes (4). In cell culture studies, α-tocopherol was found to improve the formation of an adhesive junction (known as immune synapse) between naïve T lymphocytes and antigen-presenting cells (APC), which eventually prompted T cell activation and proliferation (see Disease Prevention) (5, 6).

γ-Tocopherol and tocotrienols

Vitamin E forms other than α-tocopherol are also known to be potent antioxidants. Tocotrienols and γ-tocopherol are thought to be better scavengers of peroxyl radicals and reactive nitrogen species, respectively, than α-tocopherol (7). Yet, in the body, (1) α-tocopherol is preferentially retained in the liver by the binding to α-tocopherol transfer protein (α-TTP), which incorporates α-tocopherol into lipoproteins for delivery to extrahepatic tissues; and (2) forms of vitamin E other than α-tocopherol are actively metabolized and excreted. Hence, while γ-tocopherol is the most common form of vitamin E in the American diet (8), its plasma and tissue concentrations are generally significantly lower than those of α-tocopherol, and more γ-tocopherol is excreted in urine than α-tocopherol, suggesting less γ-tocopherol is needed for use by the body (1).

Studies conducted *in vitro* and in animals have indicated that γ-tocopherol and its major metabolite, γ-carboxyethyl hydroxychroman (γ-CEHC), may play a role in protecting the body from free radical-induced damage in various conditions of oxidative stress and inflammation (reviewed in 7). Limited intervention studies (highlighted in 7) have not convincingly demonstrated a potential anti-inflammatory effect of γ-tocopherol in humans. Yet, in two recent randomized, placebo-controlled studies, the supplementation of smokers with γ-tocopherol potentiated short-term benefits of smoking cessation (with or without nicotine replacement therapy) on vascular endothelial function (9, 10).

Numerous preclinical studies have also suggested that tocotrienols might be beneficial in the prevention of chronic diseases (11). For instance, tocotrienols (especially δ-tocotrienol) have shown greater anti-proliferative and pro-apoptotic effects than tocopherols in malignant cell lines (12). However, a number of factors, including dose, formulation, and type of study population, affect the bioavailability of tocotrienols and may undermine their putative efficacy in humans (13). There are currently no data available on the effectiveness of supplemental tocotrienols in humans (11).

Nutrient interactions

Dietary and circulating fatty acids

The mechanism of vitamin E digestion and uptake into intestinal cells (enterocytes) is unclear but requires bile acids and pancreatic enzymes, and the packaging along with dietary fat into chylomicrons. The efficiency of vitamin E absorption increases with the amount of fat in ingested food, such that vitamin E absorption from supplements is likely to be minimal with low-fat meals (14, 15).

In the circulation, all lipoproteins (i.e., VLDLs, LDLs, and HDLs) are involved in the transport and tissue distribution of α-tocopherol (1). Increased concentrations of lipids (cholesterol and triglycerides) in the blood have been correlated to higher serum α-tocopherol concentrations. However, if a high blood concentration of lipids is associated with a slower turnover of lipoproteins, then the distribution of α-tocopherol to tissues may be substantially altered (16).

Vitamin C

A few human studies using conditions of oxidative stress have demonstrated the importance of vitamin C (ascorbic acid) in the recycling of oxidized α-tocopherol back to its reduced state (see **Figure 2**). Oxidative stress caused by cigarette smoking accelerates the depletion of plasma α-tocopherol in smokers compared to nonsmokers (17). In a double-blind, placebo-controlled trial in 11 smokers and 13 nonsmokers given α-tocopherol and γ-tocopherol that was labeled with deuterium (hence traceable), supplementation with vitamin C reduced the rate of vitamin E loss in plasma, most probably by regenerating tocopheryl radicals back to nonoxidized forms (18).

Vitamin K

One study in adults with normal coagulation (clotting) status found that daily supplementation with 1,000 IU (670 mg) of *RRR*-α-tocopherol for 12 weeks decreased γ-carboxylation of prothrombin, a vitamin K-dependent factor in the coagulation cascade (19). Individuals taking anticoagulant drugs like warfarin and those who are vitamin K deficient should not take vitamin E supplements without medical supervision because of the increased risk of bleeding (see Safety) (20).

Deficiency

Causes

Severe vitamin E deficiency rarely occurs in humans but has been observed as a result of malnutrition (21). Severe vitamin E deficiency has been associated with specific genetic defects affecting the transport of α-tocopherol by α-tocopherol transfer protein (α-TTP) and lipoproteins. Vitamin E deficiency has also been observed in individuals with fat malabsorption syndromes, which impair the absorption of dietary fats and therefore fat-soluble vitamins like vitamin E (see Nutrient interactions) (21).

Symptoms

Severe vitamin E deficiency results mainly in neurologic symptoms, including impaired balance and coordination (spinocerebellar ataxia), injury to the sensory nerves (peripheral neuropathy), muscle weakness (myopathy), and damage to the retina of the eye (retinopathy). For this reason, people who develop peripheral neuropathy, ataxia, or retinitis pigmentosa (RP) of unknown causes should be screened for vitamin E deficiency (21). The results of one randomized controlled trial in 601 patients with common forms of RP indicated that daily supplementation with 400 IU of *all-rac*-α-tocopherol (180 mg of *RRR*-α-tocopherol) modestly but significantly increased the loss of retinal function (22). In contrast, daily supplementation with 15,000 IU of vitamin A (4,500 μg RAE) significantly slowed the loss of retinal function over a period of four to six years, suggesting that patients with common forms of RP may benefit from long-term vitamin A supplementation but should avoid high-dose supplemental vitamin E.

Inherited defects in α-TTP are associated with a characteristic syndrome called AVED (Ataxia with Vitamin E Deficiency). A recent case study reported that visual impairment in a middle-age patient with AVED was caused by both RP and early-onset macular degeneration (23). Supplementation with high-dose vitamin E (800-1,200 mg/day) is used to prevent neurologic deterioration in AVED subjects (21).

Moreover, the developing nervous system appears to be especially vulnerable to vitamin E deficiency. For instance, children with severe vitamin E deficiency at birth rapidly experience irreversible neurologic symptoms if not treated with vitamin E. In contrast, individuals who develop gastrointestinal disorders affecting vitamin E absorption in adulthood may not develop neurologic symptoms for 10-20 years (21). It should also be noted that neurologic symptoms caused by vitamin E deficiency have not been reported in healthy individuals who consume diets low in vitamin E.

Marginal deficiency

Although frank vitamin E deficiency is rare, marginal intake of vitamin E is relatively common. Between 1988 and 1994, the US National Health and Nutrition Examination Survey III (NHANES III) examined the dietary intake and blood concentrations of α-tocopherol in 16,295 adults. The study reported that about one-third of all participants had blood concentrations of α-tocopherol below 20 micromoles/liter (μmol/L) — a cutoff value chosen because of its initial association with an increased risk for cardiovascular disease (24). More recent data from 18,063 participants in NHANES 2003-2006 indicated an average dietary intake of α-tocopherol from food (including enriched and fortified sources) among Americans adults of 7.2 mg/day (25). This intake is well below the current recommended dietary allowance of 15 mg/day (see the RDA). At this level of dietary intake, more than 93% of American adults do not meet the estimated average requirement (EAR) of 12 mg/day for vitamin E (25). In addition, a recent nested case-control study in Bangladeshi women suggested that inadequate vitamin E status during early pregnancy may be associated with an increased risk of miscarriage (26).

Cigarette smoking is thought to increase the utilization of α-tocopherol such that smokers might be at increased risk of deficiency compared with nonsmokers (17). Also, the 19-year follow-up analysis of the Alpha-Tocopherol, Beta-Carotene cancer (ATBC) trial in older, male smokers indicated that participants in the highest versus lowest quintile of serum α-tocopherol concentrations (>31 μmol/L vs. <23 μmol/L) at baseline had reduced risks of total and cause-specific mortality (27).

It is not known whether marginal vitamin E deficiency increases the risk of chronic disease (1).

The Recommended Dietary Allowance (RDA)

The RDA for vitamin E was last revised by the Food and Nutrition Board of the US Institute of Medicine in 2000 (**Table 1**) (2). The RDA is based largely on the results of studies done in the 1950s in men fed vitamin E-deficient diets. In a test-tube analysis, vitamin E suppresses the breakdown of red blood cells (known as hemolysis) induced by hydrogen peroxide. Because hemolysis has also been reported in children with severe vitamin E deficiency, the preventive effect of vitamin E against oxidative damage-induced hemolysis was considered to be a clinically relevant *in vitro* analysis to assess vitamin E status. Importantly, this means that the latest RDA for vitamin E continues to be based on the prevention of deficiency symptoms rather than on health promotion and prevention of chronic disease.

The forms of α-tocopherol that meet the recommended intakes are *RRR*-α-tocopherol — the only naturally occurring form of vitamin E — and the three synthetic isomers, *RRS*-, *RSR*-, and *RSS*-α-tocopherol, which are found in nutritional supplements and fortified food.

Table 1 lists the RDA for α-tocopherol expressed in both milligrams (mg) and international units (IU).

Table 1. Recommended Dietary Allowance (RDA) for α-Tocopherol$^{*\#}$

Life Stage	Age	Males		Females	
		mg/day	IU/day	mg/day	IU/day
Infants (AI)	0-6 months	4	6	4	6
Infants (AI)	7-12 months	5	7.5	5	7.5
Children	1-3 years	6	9	6	9
Children	4-8 years	7	10.5	7.5	10.5
Children	9-13 years	11	16.5	11	16.5
Adolescents	14-18 years	15	22.5	15	22.5
Adults	19 years and older	15	22.5	15	22.5
Pregnancy	all ages	-	-	15	22.5
Breast-feeding	all ages	-	-	19	28.5

*These recommended intakes are limited to 2*R*-stereoisomeric forms of α-tocopherol.

$^{\#}$One mg of 2*R*-α-tocopherol is equivalent to 1.5 IU, and one IU is equivalent to 0.67 mg of 2*R*-α-tocopherol.

Disease Prevention

Age-related deterioration of immune function

The natural age-related decline of the immune function is accompanied by an increased susceptibility to infections, a poorer response to immunization, and higher risks of developing cancers and autoimmune diseases. α-Tocopherol has been shown to enhance specifically the T cell-mediated immune response that declines with advancing age (reviewed in 28). T cell impaired response has been partly associated with a reduced capacity of naïve T cells to be activated during antigen presentation, and to produce interleukin-2 (IL-2) and proliferate as a result (6). However, very few studies have addressed the potential association between α-tocopherol and immune function in humans (28). In a small intervention study in older adults (mean age, 70 years), supplementation with 200 mg/day of *all-rac*-α-tocopherol (equivalent to 100 mg of *RRR*-α-tocopherol) for three months significantly improved natural killer (NK) cytotoxic activity, neutrophil chemotaxis, phagocytic response, and enhanced mitogen-induced lymphocyte proliferation and interleukin-2 (IL-2) production compared to baseline (29). In an earlier trial, daily supplementation of healthy older adults (≥65 years of age) with 200 mg of *all-rac*-α-tocopherol for 235 days also improved T lymphocyte-mediated immunity — as measured with the delayed-type hypersensitivity (DTH) skin test — and increased the production of antibodies in response to hepatitis B and tetanus vaccines (30).

Lower α-tocopherol doses failed to improve the DTH response compared to a placebo in another study in healthy participants (ages, 65-80 years) (31). A randomized, placebo-controlled trial in 617 nursing home residents (≥65 years of age) reported that daily supplementation with 200 IU of synthetic α-tocopherol (90 mg of *RRR*-α-tocopherol) for one year significantly lowered the risk of contracting upper respiratory tract infections, especially the common cold, but had no effect on lower respiratory tract (lung) infections (32). More research is needed to examine whether supplemental vitamin E might enhance immune function and reduce risk of infection in older adults.

Cardiovascular disease

Primary prevention: in healthy adults

Observational studies: Results of several large observational studies in both men and women have suggested an inverse relationship between vitamin E consumption and risk of myocardial infarction or death from heart disease. Each study had a prospective design that measured vitamin E intake in generally healthy people who were followed over a period of time to determine the onset of cardiovascular events and analyze the association between the exposure and the outcome(s). In two of the studies, individuals who consumed more than 7 mg/day of dietary α-tocopherol were 35% less likely to die from heart disease than those who consumed less than 3-5 mg/day of α-tocopherol (33, 34). Two other large studies observed a significantly reduced risk of heart disease only in women and men who consumed at least 100 IU (67 mg)/day of supplemental *RRR*-α-tocopherol (35, 36).

Intervention studies: A randomized, placebo-controlled, intervention trial in 39,876 women (aged ≥45 years) participating in the Women's Health Study (WHS) found that supplementation with 600 IU (400 mg) of *RRR*-α-tocopherol every other day for 10 years resulted in a 34% reduction in nonfatal myocardial infarction and a 49% reduction in cardiovascular-related deaths but only in women aged at least 65 years at baseline (representing 10% of study participants) (37). Further analyses of WHS data showed that women in the vitamin E arm of the study experienced a 21% reduction in risk of venous thromboembolism (VTE) compared to placebo: the reduction was of 12% in women younger than 55 years old, 26% in women aged 65 years and older, and 44% in women with a history of VTE (38, 39). Another large randomized controlled trial — the Physicians' Health Study II (PHSII) — conducted in healthy middle-aged men found no significant effect of 400 IU of synthetic α-tocopherol (180 mg of *RRR*-α-tocopherol), given every other day for eight years, on the risk of major cardiovascular events in the entire cohort and in subgroup analyses (40). Besides, concerns were raised regarding a possible harmful effect of high-dose vitamin E supplementation on the risk of hemorrhagic stroke in this cohort (40).

Secondary prevention: in individuals with or at risk of cardiovascular disease

Conventional risk factors for cardiovascular disease (CVD) include cigarette smoking, physical inactivity, hypertension, dyslipidemia, and being overweight or obese. Other factors such as oxidative stress and inflammation are also thought to contribute to increasing CVD risk, especially in patients with chronic conditions like type 2 diabetes mellitus and chronic kidney disease. Although trials do not appear to support any cardiovascular benefit in healthy middle-aged and older subjects, vitamin E supplementation might help improve cardiovascular health and/or lower the risk of CVD in specific, higher risk subjects.

Observational studies: The presence of atherosclerotic plaques in arterial walls is one of the hallmarks of cardiovascular disease. Plaque rupture that causes blood clot formation is the usual cause of myocardial and cerebrovascular infarctions. The cross-sectional Asymptomatic Carotid Atherosclerosis Disease In Manfredonia (ACADIM) study in 640 at-risk individuals reported an inverse association between carotid intima-media thickness (CIMT) — a marker of atherosclerosis — and circulating concentrations of antioxidants, including vitamin E (41). However, other observational studies found no association between plasma vitamin E concentrations and CIMT (reviewed in 42).

Intervention studies: A small randomized controlled study assessing the effect of lipid-lowering drugs in men who had previously undergone a coronary artery bypass surgery found that the use of at least 100 IU/day (compared to less than 100 IU/day) of supplemental α-tocopherol (45 mg of *RRR*-α-tocopherol) was associated with reduced CIMT progression over a two-year period but only among participants in the placebo arm of the study (i.e., those who did not receive lipid-lowering drugs) (43). However, a recent meta-analysis of seven small placebo-controlled trials found little evidence that vitamin E supplementation may improve flow-mediated vascular dilation (FMD) of the brachial artery, a marker of vascular endothelial health that is adversely affected by CVD risk factors (44). In the Cambridge Heart AntiOxidant Study (CHAOS), a randomized, placebo-controlled intervention trial in 2,002 patients with coronary heart disease, daily supplementation with either 400 IU or 800 IU of synthetic α-tocopherol (180 mg or 360 mg of *RRR*-α-tocopherol) for a median 18 months dramatically reduced the occurrence of nonfatal myocardial infarctions by 77%. However, vitamin E supplementation did not significantly reduce total or cardiovascular-related deaths (45).

Another small trial in patients with renal failure — the Secondary Prevention with Antioxidants of cardiovascular disease in End-stage renal disease (SPACE) — found that supplementation with 800 IU (536 mg)/day of *RRR*-α-tocopherol for an average of 1.4 years significantly reduced the risk of myocardial infarction compared to placebo (46). A more recent randomized controlled study suggested that vitamin E supplementation may benefit a subgroup of patients with type 2 diabetes mellitus. The multicenter study by Milman et al. (47) was conducted in 1,434 type 2 diabetics (≥55 years old) carrying a specific variant of the haptoglobin protein (Hp), Hp2-2, which has a lower efficacy to bind and remove pro-oxidant, free hemoglobin from plasma, compared to Hp1-1 and Hp1-2 variants. The daily supplementation with 400 IU (268 mg) of *RRR*-α-tocopherol for 18 months resulted in a lower risk of myocardial infarction compared to placebo (47).

Other larger intervention trials conducted in cigarette smokers (the Alpha-Tocopherol, Beta-Carotene cancer prevention [ATBC] study (48)), in individuals at-risk of CVD (the Heart Outcomes Prevention Evaluation [HOPE]-The Ongoing Outcomes [HOPE-TOO study] (49)), or in patients who have suffered a myocardial infarction (Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto miocardico-GISSI-prevenzione trial (50)) failed to find significant CVD risk reductions with α-tocopherol supplementation. Besides, potentially harmful effects of supplemental vitamin E were reported on the risk of hemorrhagic stroke in the ATBC trial and on the risk of heart failure in the HOPE and GISSI trials (see Safety) (48-50).

Cancer

Oxidative damage to DNA by free radicals can lead to mutations that may contribute to causing cancer (51). Because of its ability to neutralize free radicals, vitamin E has been suggested to possess anticancer activity by protecting cells against oxidative damage. Yet, several large prospective cohort studies have failed to find significant associations between vitamin E intake and the incidence of lung or breast cancer (2). More recently, the VITamins And Lifestyle (VITAL) study prospectively assessed the association between long-term use of supplemental vitamins (10-year intake) and the risk of lung cancer in a cohort of 77,126 men and women (52). No relationships were reported between intake of multivitamins, vitamin C, vitamin E, or folate and the risk of lung cancer. However, the use of supplemental vitamin E in current but not in former smokers was associated with an 11% increased risk of lung cancer for every 100 mg/day increase, and intakes greater than 215 mg/day were specifically linked to a 29% increase in risk for non-small cell lung cancer (52).

To date, most clinical trials have failed to find any beneficial effects of vitamin E supplementation on the risk of various cancers. A randomized, placebo-controlled trial (RCT) in 39,876 women participating in the Women's Health Study found that supplementation with 600 IU (400 mg) of *RRR*-α-tocopherol every other day for 10 years had no effect on overall cancer incidence, tissue-specific cancer incidence, or cancer-related deaths (37). Yet, the results of a few large randomized controlled trials have suggested that vitamin E supplementation might affect the risk of prostate cancer. The Alpha-Tocopherol, Beta-Carotene cancer (ATBC) prevention study was a four-arm, randomized, double-blind, placebo-controlled trial designed to investigate the effect of α-tocopherol supplementation on lung cancer development in 29,133 male smokers. The study found a 32% reduction in the incidence of prostate cancer in participants given daily supplements of 50 mg of synthetic α-tocopherol (equivalent to 25 mg of *RRR*-α-tocopherol) alone or in combination with β-carotene compared to those given β-carotene alone or a placebo (53). However, no differences in the incidence of prostate cancer were found between α-tocopherol recipients and nonrecipients during the 18-year post-intervention period (54). In the Physicians' Health Study II (PHS II), which followed 14,641 healthy men aged 50 years and older, supplementation with 400 IU of synthetic vitamin E (equivalent to 180 mg of *RRR*-α-tocopherol) every other day for eight years had no effect on the risk of prostate cancer, other site-specific cancers, or total cancer (55). The supplementation of vitamin E (equivalent to 180 mg/day of *RRR*-α-tocopherol), alone or in combination with selenium, in the multicenter, randomized, placebo-controlled SELECT trial (SELenium and vitamin E Cancer prevention Trial) was halted because there was no evidence of benefit in preventing prostate cancer in 35,533 healthy men aged 50 years and older (56). After a median of seven years' follow-up, the risk of prostate cancer was found to be significantly increased by 17% in participants supplemented with vitamin E alone during the trial period — but not when vitamin E was combined with selenium — compared to placebo (57). A study of cases versus subcohort individuals drawn from the SELECT study assessed the effect of vitamin E and/or selenium supplementation on prostate cancer risk in relation to the selenium status of participants at baseline (58). Supplemental selenium with or without vitamin E was associated with a significant increase in the risk of advanced prostate cancer in individuals with higher versus lower selenium status. In addition, the risks of total and advanced prostate cancer were significantly elevated with vitamin E supplementation in subjects with low versus high selenium status (58). Recent investigations have suggested that sequence variations (polymorphisms) in vitamin E-related genes and genes coding for antioxidant enzymes, including selenoproteins, might modify the impact of high-dose vitamin E and selenium on the risk of prostate cancer (59-61).

Cataracts

Age-related cataracts appear to be the result of protein oxidation in the lens of the eye; antioxidants like α-tocopherol may protect the lens against oxidative damage from reactive oxygen species. In a recent cross-sectional study, vitamin E concentrations were found to be significantly lower in the lens and blood of subjects with age-related nuclear, but not cortical, cataracts when compared with an age-matched control group (62). However, earlier studies reported higher vitamin E concentrations in the lenses and blood of patients with cataracts (63, 64).

The results of several observational studies that examined the association between vitamin E consumption and the incidence or severity of cataracts are also mixed. Some reported that increased vitamin E intake protected against cataract development, while others found no association (65). Yet, a meta-analysis of eight studies, including 15,021 participants, found a 17% reduction in the risk of age-related cataract in subjects in the highest versus lowest quantile of dietary vitamin E intake (66). A recent prospective cohort study of 31,120 Swedish men followed for a mean of 8.4 years observed a greater risk of developing cataract in occasional and regular users of high-dose (about 100 mg/day) vitamin E supplements only, when compared with non-supplement users (67). However, the use of supplemental high-dose vitamin E with additional supplements or the use of low-dose vitamin E-containing multivitamin supplements was not found to be associated with an elevated cataract risk. A meta-analysis based on data from over 350,000 participants in 10 studies — including the above-cited study by Zheng Selin et al. (67) — found no association between supplemental vitamin E and risk of cataract (66).

In clinical settings, the supplementation of high-dose vitamin E — alone or in addition to other supplements — was found to be safe, yet the benefits regarding cataract risk or progression were limited. An early intervention trial found that a daily supplement of 50 mg of synthetic α-tocopherol (equivalent to 25 mg of *RRR*-α-tocopherol) did not alter the incidence of cataract surgery in male smokers (68). A randomized, placebo-controlled intervention trial in 4,629 men and women found that a daily antioxidant supplement containing 500 mg of vitamin C, 400 IU of *all-rac*-α-tocopheryl acetate (equivalent to 180 mg of *RRR*-α-tocopherol), and 15 mg of β-carotene did not affect development and progression of age-related cataracts over a seven-year period (69). Similarly, a four-armed, randomized, placebo-controlled study of 11,267 men from the Selenium and Vitamin E Cancer prevention trial (SELECT) failed to observe a reduction in cataract incidence with 400 IU/day of supplemental *all-rac*-α-tocopheryl acetate (180 mg/day of *RRR*-α-tocopherol), alone or in combination with selenium (200 μg/day), during a mean 5.6 years of follow-up (70). Daily antioxidant supplementation with 500 mg of vitamin C, 400 IU (268 mg) of *RRR*-α-tocopherol, and 15 mg of β-carotene did not limit the progression of cataract in a five-year intervention trial (71). Another four-year randomized, placebo-controlled trial reported that supplements containing 500 IU/day (335 mg/day) of *RRR*-α-tocopherol did not reduce the incidence or progression of cataract in older adults (72). Current available data from clinical trials do not support a preventative effect of vitamin E on cataracts.

Disease Treatment

Age-related macular degeneration

A recent pooled analysis of four randomized controlled trials in 62,520 subjects found that supplemental vitamin E or β-carotene did not reduce the risk of developing age-related macular degeneration (AMD), a multifactorial disease affecting the central area of the retina (73). However, a review of currently available data suggested that supplements of antioxidants plus zinc may reduce the progression of AMD and vision loss in affected individuals (74). The main evidence came from the Age-Related Eye Disease Study (AREDS). In this clinical trial, participants with borderline to advanced age-related macular degeneration (AMD) were randomized to receive (1) placebo; (2) antioxidant vitamins (15 mg/day of β-carotene, 500 mg/day of ascorbic acid, and 400 IU/day of *all-rac*-α-tocopheryl acetate); (3) zinc (80 mg/day) and copper (2 mg/day); or (4) both antioxidant vitamins and zinc and copper (75). The five-year results indicated that the risk of developing advanced AMD was significantly reduced in those taking zinc with or without antioxidant vitamins. Antioxidant vitamins alone failed to prevent the progression to advanced AMD, even in individuals at higher risk. It was concluded from this study that a combination of antioxidant vitamins and minerals may benefit people with intermediate AMD or advanced AMD in one eye (74, 76).

Type 2 diabetes mellitus

Oxidative stress contributes to the progression of type 2 diabetes mellitus and causes damage to many organs and tissues, including the pancreas, brain, eyes, peripheral nerves, and kidneys. Evidence from animal studies suggests that vitamin E supplementation could mitigate the role of oxidative damage in the occurrence of diabetes complications (reviewed in 77). In the Alpha-Tocopherol Beta-Carotene cancer prevention (ATBC) trial in male smokers, supplementation with 50 mg/day of synthetic α-tocopherol (25 mg/day of *RRR*-α-tocopherol) had no effect on the risk of incident type 2 diabetes mellitus during the 19-year post-intervention follow-up. Likewise, supplemental vitamin E intake during the trial made no difference on the incidence of macrovascular complications or mortality in participants with established type 2 diabetes (78). In addition, a meta-analysis of 14 heterogeneous randomized controlled trials, including 714 type 2 diabetic individuals, found that supplementation with vitamin E (200-1,800 IU/day for 6-27 weeks) had no effect on markers of glycemic control, including glycated hemoglobin A1c (HbA1c) level and measures of fasting glucose and fasting insulin concentrations (79). Further subgroup analyses indicated that higher doses of vitamin E (>400 IU/day) supplemented for longer periods (>12 weeks) significantly reduced HbA1c level and fasting insulin concentration, suggesting that vitamin E could possibly enhance insulin action and glucose disposal in type 2 diabetic individuals (79). Another recent meta-analysis of randomized controlled trials found that endothelial function in normal-weight and overweight — but not obese — patients with type 2 diabetes was significantly improved by supplementation with vitamin E and/or vitamin C (80). Although there is reason to suspect that vitamin E supplementation may have utility in the management of type 2 diabetes, evidence for benefit from large, well-controlled clinical trials is still lacking.

Fatty liver diseases

The increasing incidence of nonalcoholic fatty liver disease (NAFLD) in children and adults in industrialized countries is mainly attributed to the ongoing epidemic of obesity and type 2 diabetes mellitus. NAFLD results from the abnormal accumulation of fat (steatosis) in the liver in the absence of heavy alcohol consumption. Although the condition is considered to be largely benign, NAFLD can progress to a more severe disease called nonalcoholic steatohepatitis (NASH) with increased risks of cirrhosis, hepatocellular carcinoma (liver cancer), and cardiovascular disease (81). Oxidative stress is thought to be one of the possible mechanisms responsible for prompting inflammatory processes that can lead to the progression of NAFLD to NASH.

There is currently no established treatment for NAFLD and NASH other than interventions that encourage lifestyle changes and the use of medicines to control or treat metabolic disorders (82). In the multicenter PIVENS (PIoglitazone versus Vitamin E versus placebo for the treatment of Nonalcoholic Steatohepatitis) trial, 247 nondiabetic subjects with NASH were randomized to receive 30 mg/day of pioglitazone (an insulin-sensitizing drug), 800 IU/day (536 mg/day) of *RRR*-α-tocopherol, or a placebo for 96 weeks (83). Only vitamin E supplementation significantly increased the overall rate of improvement in histological abnormalities that characterize NASH on liver biopsies (i.e., hepatocellular ballooning, steatosis, and lobular inflammation) (84). Both active treatments improved some markers of liver function (i.e., alanine aminotransferase and aspartate aminotransferase) (84). Yet, results from another two-year, randomized controlled trial — called TONIC for Treatment Of Nonalcoholic fatty liver disease In Children — in 173 children (ages, 8-17 years) with NAFLD failed to observe any significant reduction in blood concentrations of alanine and aspartate aminotransferases either with supplemental vitamin E (536 mg/day of *RRR*-α-tocopherol) or with metformin (an anti-diabetic drug; 1,000 mg/day) compared to placebo (85). However, vitamin E supplementation significantly improved the overall disease activity score — used to quantify the severity of the disease. In addition, a recent meta-analysis of another six trials found that vitamin E significantly lowered circulating aminotransferase concentrations in NAFLD and NASH patients, suggesting liver function improvements (86). Finally, in a small nonrandomized, unblinded, controlled study in 42 obese children (mean age, 8 years) with NAFLD, lifestyle recommendations combined with 600 mg/day of supplemental *RRR*-α-tocopheryl acetate for six months reduced markers of oxidative stress and liver dysfunction and improved insulin sensitivity and the profile of lipid in the blood, when compared to baseline. No such changes in markers of oxidative stress, liver function, and glucose utilization were reported in the lifestyle intervention only group (87). Further randomized and well-controlled studies are needed to confirm these preliminary findings.

Cognitive deterioration and Alzheimer's disease

Mitochondrial dysfunction and oxidative stress are thought to contribute to the onset and/or progression of several neurodegenerative diseases, especially Alzheimer's disease (AD) (88). The progressive degeneration of neuronal cells that accompanies the decline of memory and other cognitive functions in subjects with Alzheimer's disease is associated with an intracellular aggregation of Tau fibrils, an extraneuronal accumulation of β-amyloid peptides into senile plaques, and an oxidation-reduction (redox) imbalance of complex etiology. In the brain of patients with mild cognitive impairment (MCI) and those with AD, the level of markers of oxidative damage to DNA, proteins, and lipids is increased, while the expression and activities of glutathione and antioxidant enzymes are reduced (reviewed in 88). In addition, a recent meta-analysis reported that circulating concentrations of vitamins, including vitamin A, vitamin C, and vitamin E, were significantly lower in AD patients than in cognitively healthy individuals (89). Other studies have documented low concentrations of vitamin E in cerebrospinal fluid of cognitively impaired patients (reviewed in 90).

Because a reduction in oxidative stress may help maintain cognitive status and/or prevent deterioration, the effects of vitamin E supplementation have been assessed in a few intervention studies. An early multicenter, randomized, placebo-controlled study in individuals with AD of moderate severity found that supplementation with 2,000 IU/day of *all-rac*-α-tocopherol (equivalent to 900 mg/day of *RRR*-α-tocopherol) for two years significantly delayed cognitive decline, slowed disease progression, and increased median survival (91). However, a placebo-controlled trial in 769 patients with MCI found that the same dosage of vitamin E did not affect the probability of progression from MCI to AD over a three-year period (92). In another double-blind, placebo-controlled trial, an improvement in cognitive performance — measured by the Mini Mental State Examination (MMSE) scoring system — was reported in AD patients randomized to receive 800 IU/day of *all-rac*-α-tocopherol (360 mg/day of *RRR*-α-tocopherol) for six months only when the treatment effectively reduced oxidative stress (as assessed by the measure of total glutathione and markers of lipid peroxidation in the blood) (93). Conversely, a failure to reduce oxidative stress resulted in supplemental vitamin E being more detrimental to the cognitive function of AD patients than placebo. In the most recent multicenter, randomized, double-blind, placebo-controlled study, supplemental vitamin E (2,000 IU/day; form of vitamin E not mentioned in the publication) for over two years significantly delayed functional decline — determined by the (in)ability to perform basic activities of daily living — and reduced the annual mortality rate in mild and moderate AD patients (94). Yet, vitamin E failed to affect cognitive performance measured with MMSE scores and other cognitive ability tests.

While there is currently little evidence to suggest that long-term supplementation of vitamin E provides any cognitive benefits in healthy older adults (95), additional research needs to confirm whether vitamin E supplementation could benefit the management of patients with mild-to-moderate cognitive impairments.

Sources

Food sources

Major sources of α-tocopherol in the American diet include vegetable oils (olive, sunflower, and safflower oils), nuts, whole grains, and green leafy vegetables. All eight forms of vitamin E (α-, β-, γ-, and δ-tocopherols and α-, β-, γ-, and δ-tocotrienols) occur naturally in mostly plant-based foods but in varying amounts. **Table 2** lists the content of α-tocopherol and γ-tocopherol (in milligrams) in some rich sources of vitamin E. For more information on the vitamin E content of foods, search USDA's FoodData Central.

Table 2. Some Food Sources of Vitamin E

Food	Serving	α-Tocopherol (mg)	γ-Tocopherol (mg)
Sunflower oil	1 tablespoon	5.6	0.6
Safflower oil	1 tablespoon	4.6	-
Grapeseed oil	1 tablespoon	3.9	-
Canola oil	1 tablespoon	2.4	3.8
Corn oil	1 tablespoon	1.9	-
Olive oil	1 tablespoon	1.9	0.1
Soybean oil	1 tablespoon	1.1	8.7
Sunflower seed kernels, dry roasted	1 ounce	7.4	0
Almonds	1 ounce	7.3	0.2
Hazelnuts	1 ounce	4.3	0
Peanuts	1 ounce	2.4	2.4
Pecans	1 ounce	0.4	6.9
Peanut butter, smooth	2 tablespoons	3.2	-
Tomato sauce, canned	1 cup	3.5	0.2
Cranberry juice	1 cup (8 fl oz)	3.0	-
Apricots, dried	½ cup (halves)	2.8	0
Avocado (California)	1 fruit	2.7	0.4
Fish, rainbow trout, cooked, dry-heat	3 ounces	2.4	0
Spinach, cooked, boiled	½ cup	1.9	-
Asparagus, canned	½ cup	1.5	-
Swiss chard, cooked, boiled	½ cup (chopped)	1.6	-
Broccoli, cooked, boiled	½ cup (chopped)	1.1	-
Blackberries, raw	½ cup	0.8	0.3

In the US, the average intake of α-tocopherol from food (including enriched and fortified sources) for adults (≥19 years of age) is 7.2 mg/day (25); this level is well below the RDA of 15 mg/day of α-tocopherol (see **Table 1**). While it appears feasible for individuals to meet the RDA from food only, Americans would have to depart from their current dietary practices and include greater intakes of nuts, seeds, fruit, and vegetables without increasing fat intake above recommended levels (96).

Supplements

RRR-α-tocopherol is the only stereoisomeric form of α-tocopherol found in unfortified foods. The same is not always true for nutritional supplements. Vitamin E supplements generally contain 100 IU to 1,000 IU of α-tocopherol. Supplements made from entirely natural sources contain only *RRR*-α-tocopherol (wrongly labeled *d*-α-tocopherol). *RRR*-α-tocopherol is the most bioavailable form of α-tocopherol in the body. Synthetic α-tocopherol, which is often found in fortified food and nutritional supplements and usually labeled *all-rac*-α-tocopherol or *dl*-α-tocopherol, include all eight possible stereoisomers of α-tocopherol (see Function). Because half of the isomers present as a mixture in synthetic α-tocopherol are not usable by the body, synthetic α-tocopherol is less bioavailable than natural α-tocopherol (see **Figure 1**). To calculate the amount (in milligrams) of α-tocopherol bioavailable in a supplement, the conversion factors are as follows:

- Natural vitamin E (*RRR*-α-tocopherol) containing supplements:
  IU of *RRR*-α-tocopherol x 0.67 = mg of *RRR*-α-tocopherol
  Example: 100 IU of natural vitamin E provides 67 mg of *RRR*-α-tocopherol
- Synthetic vitamin E (*all-rac*-α-tocopherol) containing supplements:
  IU of *all-rac*-α-tocopherol x 0.45 = mg of *RRR*-α-tocopherol
  Example: 100 IU of synthetic vitamin E provides 45 mg of 2*R*-α-tocopherol

In addition, vitamin E-fortified foods often contain synthetic α-tocopherol, and amounts of vitamin E are provided as a percentage of the daily value (DV) of 30 IU (approximately 20 mg of *RRR*-α-tocopherol).

α-Tocopheryl esters

α-Tocopheryl succinate and α-tocopheryl acetate are the main esterified forms of vitamin E in nutritional supplements. Tocopherol esters are more resistant to oxidation during storage than unesterified tocopherols (1). When taken orally, the succinate or acetate moieties are removed from α-tocopherol in the intestine. The bioavailability of α-tocopherol from α-tocopheryl succinate and α-tocopheryl acetate is equivalent to that of free α-tocopherol (97). Hence, the conversion factors used to determine the amount of bioavailable α-tocopherol provided by α-tocopheryl succinate and α-tocopheryl acetate are the same as those used for α-tocopherol (see above) (2). Cell culture studies indicated that the vitamin E ester, α-tocopheryl succinate, could inhibit proliferation and induce apoptosis in a number of cancer cell lines (12). Limited data from animal models of cancer found that α-tocopheryl succinate administered by injection inhibited tumor growth (98). There is currently no evidence in humans that taking oral α-tocopheryl succinate supplements delivers α-tocopheryl succinate to tissues. Of note, current research investigates nanomedicines to increase α-tocopheryl succinate bioavailability before exploring putative benefits in clinical settings (98).

α-Tocopheryl nicotinate is another α-tocopherol ester formed from synthetic α-tocopherol and nicotinic acid (niacin). While α-tocopheryl nicotinate can be prescribed as a lipid-lowering agent in Europe and Japan, it is marketed as a supplement only in the US (99).

α-Tocopheryl phosphates (Ester-E®)

There is currently no published evidence that supplements containing α-tocopheryl phosphates are more efficiently absorbed or have greater bioavailability in humans than those containing α-tocopherol (99).

Other supplemental forms

Supplements containing γ-tocopherol, mixed tocopherols, or tocotrienols are also commercially available (99). The amounts of α- and γ-tocopherol in mixed tocopherol supplements vary, so it is important to read the label to determine the amount of each tocopherol form present in a capsule.

Safety

Toxicity

Few side effects have been noted in adults taking supplements of less than 2,000 mg of α-tocopherol daily (either natural or synthetic vitamin E). However, most studies assessing safety issues or toxicity of α-tocopherol supplementation have lasted only a few weeks to a few months, and side effects associated with long-term α-tocopherol supplementation have not been adequately studied. The most worrisome possibility is that of impaired blood clotting, which increases the likelihood of hemorrhage in some individuals. A meta-analysis of randomized controlled trials found that daily vitamin E supplementation — equivalent to 25 to 536 mg/day of *RRR*-α-tocopherol — for several years resulted in a significant, 10% reduction in the risk of ischemic stroke (five trials, 91,393 participants) and a nonsignificant trend towards an increased risk of hemorrhagic stroke (five trials, 100,748 participants) (100).

A tolerable upper intake level (UL) for any form of supplemental α-tocopherol (all possible stereoisomers) has been established by the Food and Nutrition Board of the Institute of Medicine to avoid the potential risk of bleeding (**Table 3**). Specifically, the UL of 1,000 mg/day of α-tocopherol in any supplemental form (equivalent to 1,500 IU/day of *RRR*-α-tocopherol or 1,100 IU/day of *all-rac*-α-tocopherol) corresponds to the highest dose unlikely to result in hemorrhage in almost all adults (2). Although only certain isomers of α-tocopherol are retained in the circulation, all forms are absorbed and metabolized by the liver. Hence, the rationale for a UL that refers to all stereoisomers of α-tocopherol is based on the fact that any form of α-tocopherol (natural or synthetic) can be absorbed and thus be potentially harmful.

Table 3. Tolerable Upper Intake Level (UL) for α-Tocopherol*

Age Group	mg/day$^{\#}$
Infants 0-12 months	Not possible to establish$^{\#\#}$
Children 1-3 years	200
Children 4-8 years	300
Children 9-13 years	600
Adolescents 14-18 years	800
Adults 19 years and older	1,000

*The UL for α-tocopherol applies to all stereoisomers of α-tocopherol (natural and synthetic) found in supplements and fortified food.

$^{\#}$Of note, mg-to-IU conversion factors are such that the UL in IU for synthetic tocopherol (*all-rac*-α-tocopherol) is 1.10 times the UL in mg, and the UL in IU for natural tocopherol (*RRR*-α-tocopherol) is 1.50 times the UL in mg. Hence, the UL amount of 1,000 mg for adults corresponds to 1,100 IU of synthetic tocopherol or 1,500 IU of natural tocopherol.

$^{\#\#}$Source of intake should be from foods or formula only.

Some physicians recommend discontinuing high-dose vitamin E supplementation two to four weeks before elective surgery — including dental procedures — to decrease the risk of hemorrhage (99).

Because dietary vitamin E is essential to prevent vitamin E deficiency in the newborn, vitamin E must be supplied in parenteral nutrition solutions in infants who cannot be given enteral feeding, such as prematurely born infants. Yet, preterm infants appear to be especially vulnerable to adverse effects of α-tocopherol supplementation, and supplemental vitamin E should be administered only under controlled supervision by a pediatrician (101).

Finally, the results of only one randomized controlled trial in 601 patients with common forms of retinitis pigmentosa (RP) indicated that supplementation with 400 IU/day of synthetic vitamin E (equivalent to 180 mg/day of *RRR*-α-tocopherol) modestly but significantly accelerated the loss of retinal function compared to placebo (22). Patients with common forms of RP should therefore avoid taking high-dose vitamin E supplements if they are not deficient in vitamin E (see Deficiency).

Does vitamin E supplementation increase the risk of all-cause mortality?

A prospective observational study in over 4,000 participants of the Framingham Heart Study and the Framingham Offspring Study — with or without preexisting cardiovascular disease — found no statistically significant association between vitamin E supplement intake and cardiovascular or all-cause mortality after a 10-year follow-up period (102). However, in addition to reports of increased risk of hemorrhage and heart failure with supplemental vitamin E in several randomized controlled studies (see Cardiovascular disease), a meta-analysis by Miller et al. (103) suggested an increased risk of death with the use of large doses of vitamin E, yet lower than the UL. Specifically, this meta-analysis combined the results of 19 clinical trials of vitamin E supplementation that mostly focused on secondary prevention and, as such, included subjects with pre-existing conditions including heart disease, end-stage renal failure, and Alzheimer's disease. The study found that daily supplementation with at least 400 IU of synthetic vitamin E (equivalent to 180 mg of *RRR*-α-tocopherol) resulted in a 4% increase in risk of death from any cause compared to placebo (103). However, further dose-response analysis and adjustment for intake of other vitamin and mineral supplements indicated that all-cause mortality risk was significantly increased by 7% only at a dose of 2,000 IU/day, which is notably higher than the UL for adults (1,100 IU/day of synthetic tocopherol or 1,500 IU/day of natural tocopherol; see **Table 3**). Additionally, a more recent meta-analysis of 46 randomized trials, including 171,244 participants, found that supplemental vitamin E, singly or in combination with other antioxidants, did not significantly alter the risk of all-cause mortality (104). At present, there is no convincing evidence that vitamin E supplementation below the UL increases the risk of death from cardiovascular disease or other causes, especially in generally healthy subjects. Yet, individuals with pre-existing conditions may be at increased risk of serious adverse effects (including death) if one considers the possibility that large doses of supplemental vitamin E might interfere with medications, and possibly lower their efficacy or increase their toxicity (1).

Nutrient interactions

Large doses of vitamin E may inhibit vitamin K-dependent carboxylase activity and interfere with the coagulation cascade (see the article on Vitamin K) (19). Hence, the use of vitamin E supplements may increase the risk of bleeding in individuals taking anticoagulant drugs (blood thinners), such as heparin and the vitamin K antagonist, warfarin (Coumadin); antiplatelet drugs, such as clopidogrel (Plavix), ticlopidine (Ticlid), tirofiban (Aggrastat), and dipyridamole (Aggrenox); and non-steroidal anti-inflammatory drugs (NSAIDs), including aspirin, ibuprofen, and others. In addition, individuals who may be vitamin K deficient due to liver failure, those with a propensity to bleed (e.g., bleeding peptic ulcers), and those with inherited bleeding disorders (e.g., hemophilia) or a history of hemorrhagic stroke, should not take α-tocopherol supplements without close medical supervision because of the increased risk of hemorrhage (20, 99). Finally, it cannot be excluded that vitamin E would potentiate the antithrombotic activity of supplemental fish oils and herbal products, such as garlic, curcumin, or Ginkgo biloba (99).

Drug interactions

A number of cholesterol-lowering medications (like cholestyramine and colestipol), as well as orlistat, sucralfate, mineral oil, and the fat substitute, olestra, which interfere with fat absorption, may theoretically decrease the absorption of fat-soluble vitamins, including vitamin E. The anticonvulsant drugs phenobarbital, phenytoin (Dilantin), and carbamazepine (Tegretol), may also lower plasma vitamin E concentrations in individuals with epilepsy (105).

Antioxidants and statins (3-hydroxy-3-methylglutary-coenzyme A reductase inhibitors)

A three-year randomized controlled trial in 160 patients with coronary heart disease (CHD) and low high-density-lipoprotein (HDL) levels found that a combination of simvastatin (Zocor) and niacin increased the HDL2 subfraction level (considered the most cardioprotective), inhibited the progression of coronary artery stenosis (narrowing), and decreased the frequency of cardiovascular events, such as myocardial infarction and stroke (106). Surprisingly, when an antioxidant combination of 1,000 mg of vitamin C, 800 IU (536 mg) of *RRR*-α-tocopherol, 100 μg of selenium, and 25 mg of β-carotene daily, was taken with the simvastatin-niacin combination, the protective effects were diminished. However, in a much larger randomized controlled trial of simvastatin and an antioxidant combination of 600 mg of *all-rac*-α-tocopherol (297 mg of *RRR*-α-tocopherol), 250 mg of vitamin C, and 20 mg of β-carotene daily in more than 20,000 men and women with CHD or diabetes, the antioxidant combination did not adversely affect the cardioprotective effects of simvastatin therapy over a five-year period (107). These contradictory findings indicate that further research is needed on potential interactions between antioxidant supplementation and cholesterol-lowering agents like statins.

Linus Pauling Institute Recommendation

The Recommended Dietary Allowance (RDA) for vitamin E for adult men and women is 15 mg (22.5 IU) per day. Notably, more than 90% of individuals two years of age and older in the US do not meet the daily requirement for vitamin E from food sources alone. Therefore, LPI recommends that generally healthy adults (aged 19 years and older) take a daily multivitamin/mineral (MVM) supplement, which usually contains 30 IU of synthetic vitamin E — equivalent to 13.5 mg of *RRR*-α-tocopherol and 90% of the RDA.

Older adults (>50 years)

The Linus Pauling Institute's recommendation to take a daily multivitamin/mineral (MVM) supplement containing vitamin E is also appropriate for generally healthy older adults. MVMs typically contain 30 IU of synthetic vitamin E, covering 90% of the RDA.

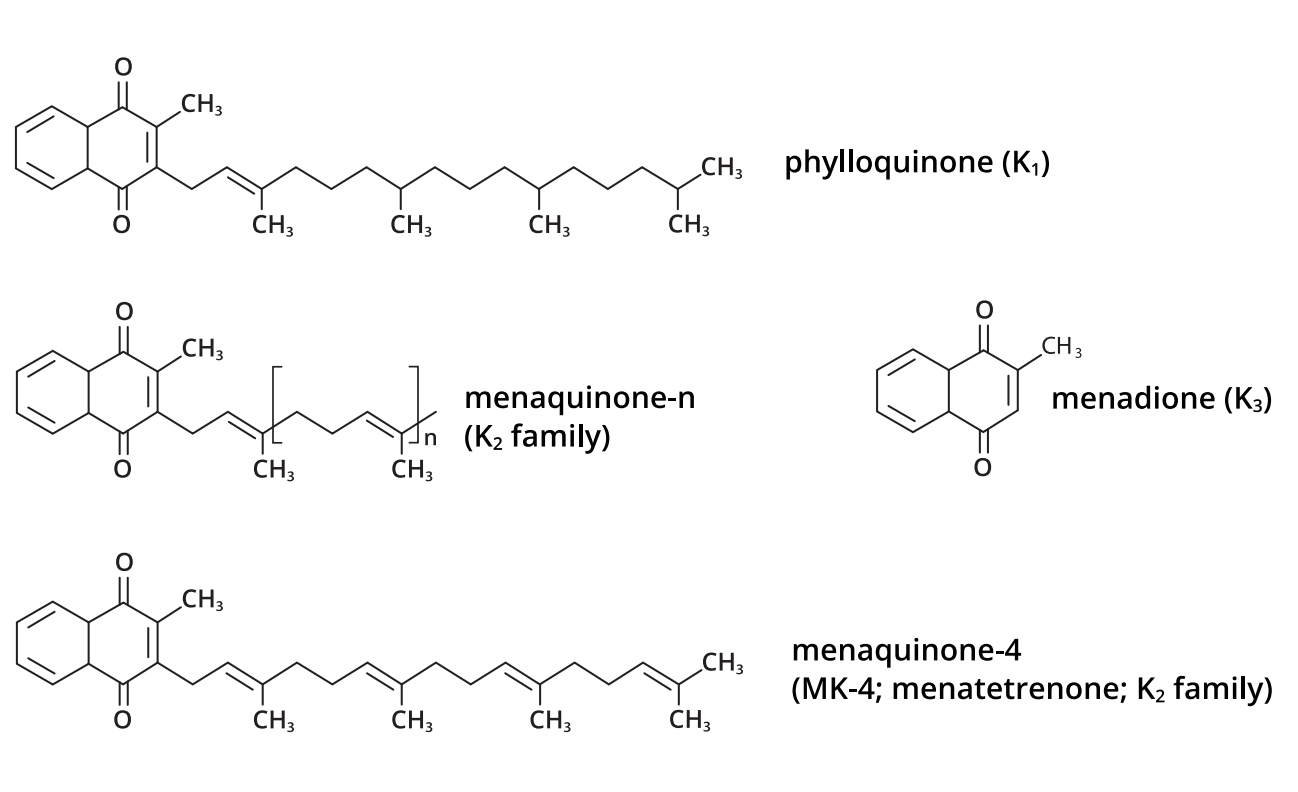
Summary

- Naturally occurring forms of vitamin K include phylloquinone (vitamin K_1) and a family of molecules called menaquinones (MKs or vitamin K_2). *(More information)*
- With limited vitamin K storage capacity, the body recycles vitamin K in the vitamin K oxidation-reduction cycle in order to reuse it multiple times. *(More information)*
- Vitamin K is the essential cofactor for the carboxylation of glutamic acid residues in many vitamin K-dependent proteins (VKDPs) that are involved in blood coagulation, bone metabolism, prevention of vessel mineralization, and regulation of various cellular functions. *(More information)*
- Vitamin K deficiency increases the risk of excessive bleeding (hemorrhage). An injection of vitamin K is recommended to protect all newborns from life-threatening bleeding within the skull. *(More information)*
- The adequate intake (AI) level for vitamin K is set at 90 μg/day for women and 120 μg/day for men. *(More information)*
- Vitamin K deficiency may impair the activity of VKDPs and increase the risk of osteoporosis and fractures. Some, but not all, observational studies have found lower vitamin K status to be associated with lower bone mineral density and higher fracture incidence. Overall, intervention trials have been inconclusive regarding the role of supplemental vitamin K (vitamin K_1 or vitamin K_2) in further reducing bone loss in otherwise calcium- and vitamin D-replete adults. *(More information)*
- Abnormal mineralization of blood vessels increases with age and is a major risk factor for cardiovascular disease. Vitamin K inadequacy may inactivate several VKDPs that inhibit the formation of calcium precipitates in vessels. There is only limited evidence of a benefit of supplemental vitamin K in the prevention of vessel calcification and cardiovascular events. *(More information)*
- While the results of a few observational studies suggest that low vitamin K status might have a role in development of osteoarthritis, randomized controlled trials are needed. *(More information)*
- Phylloquinone is found at high concentrations in green leafy vegetables and certain plant oils, while most menaquinones are usually found in cheese, animal products, and certain fermented foods. *(More information)*
- Several drugs, including vitamin K antagonists (e.g., warfarin), are known to interfere with vitamin K absorption and metabolism. *(More information)*

Vitamin K is a fat-soluble vitamin. Originally identified for its role in the process of blood clot formation ("K" is derived from the Danish word "koagulation"), vitamin K is essential for the functioning of several proteins involved in physiological processes that encompass, but are not limited to, the regulation of blood clotting (coagulation) (1). Naturally occurring forms of vitamin K include a number of vitamers known as vitamin K_1 and vitamin K_2 (**Figure 1**). Vitamin K_1 or phylloquinone is synthesized by plants and is the predominant form in the diet. Vitamin K_2 includes a range of vitamin K forms collectively referred to as menaquinones. Most menaquinones are synthesized by human intestinal microbiota and found in fermented foods and in animal products. Menaquinones differ in length from 1 to 13 repeats of 5-carbon units in the side chain of the molecules. These forms of vitamin K are designated menaquinone-n (MK-n), where n stands for the number of 5-carbon units (MK-2 to MK-13) (2, 3). Widely used in animal husbandry, the synthetic compound known as menadione (vitamin K_3) is a provitamin that needs to be converted to menaquinone-4 (MK-4) to be active (**Figure 1**) (4).

Figure 1. Chemical Structures of Vitamin K



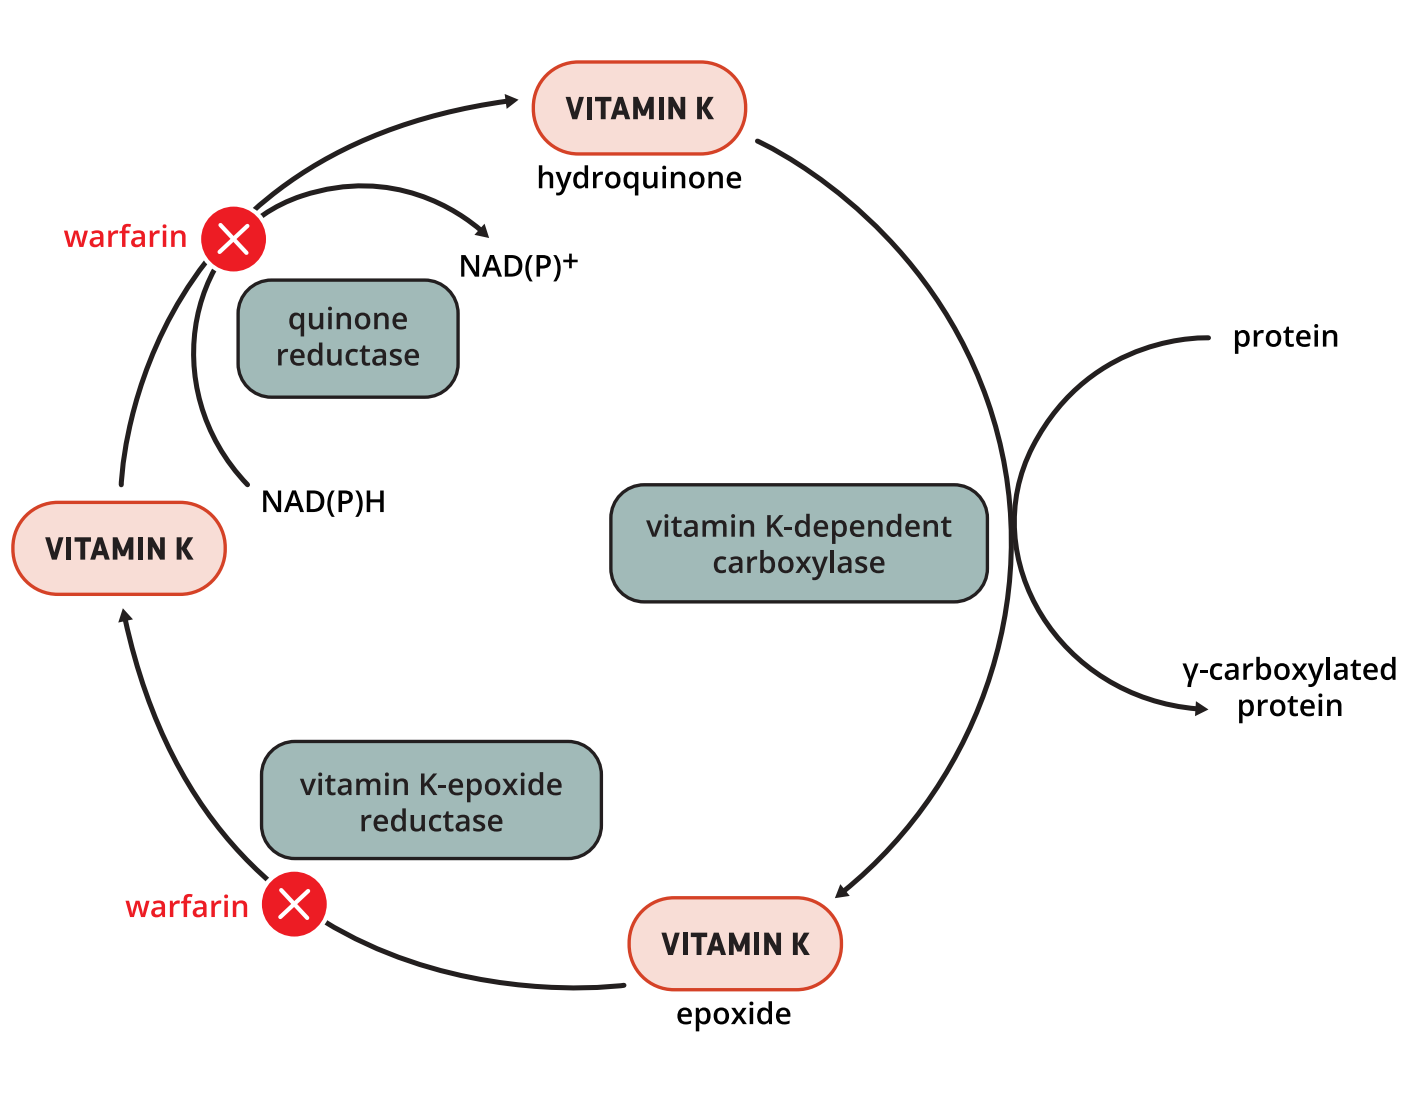
Function

Vitamin K functions as a cofactor for the enzyme, γ-glutamylcarboxylase, which catalyzes the carboxylation of the amino acid glutamic acid (Glu) to γ-carboxyglutamic acid (Gla). Vitamin K-dependent γ-carboxylation that occurs only on specific glutamic acid residues in identified vitamin K-dependent proteins (VKDP) is critical for their ability to bind calcium (5).

Vitamin K oxidation-reduction cycle

Although vitamin K is a fat-soluble vitamin, the body stores very small amounts that are rapidly depleted without regular dietary intake. Perhaps because of its limited ability to store vitamin K, the body recycles it through a process called the vitamin K-epoxide cycle (**Figure 2**). The vitamin K cycle allows a small amount of vitamin K to be reused many times for protein carboxylation, thus decreasing the dietary requirement. Briefly, vitamin K hydroquinone (reduced form) is oxidized to vitamin K epoxide (oxidized form). The reaction enables γ-glutamylcarboxylase to carboxylate selective glutamic acid residues on vitamin K-dependent proteins. The recycling of vitamin K epoxide (oxidized form) to hydroquinone (reduced form) is carried out by two reactions that reduce vitamin K epoxide (KO) to vitamin K quinone and then to vitamin K hydroquinone (KH_2; **Figure 2**). Additionally, the enzyme vitamin K-epoxide reductase (VKOR) catalyzes the reduction of KO to vitamin K quinone and may be involved — as well as another yet-to-defined reductase — in the production of KH2 from vitamin K quinone (6, 7). The anticoagulant drug warfarin acts as a vitamin K antagonist by inhibiting VKOR activity, hence preventing vitamin K recycling (see Coagulation).

Figure 2. The Vitamin K Cycle



The reduced form of vitamin K (hydroquinone) donates a pair of electrons to the vitamin K-dependent carboxylase (known as γ-glutamylcarboxylase), which carboxylates glutamic acid residues in specific vitamin K-dependent proteins. The resultant oxidized form of vitamin K (epoxide) is converted back to hydroquinone in a two-step reaction. The first step, which converts vitamin K epoxide to vitamin K, is catalyzed by vitamin K-epoxide reductase; the second step is catalyzed by either vitamin K-epoxide reductase or most likely by another yet-to-be-defined reductase. This pathway is inhibited by the vitamin K antagonist and anticoagulant drug, warfarin. The reduction of vitamin K to hydroquinone is also possibly catalyzed by a NAD(P)H-dependent reductase that is resistant to warfarin.

Coagulation

The ability to bind calcium ions (Ca^{2+}) is required for the activation of the several vitamin K-dependent clotting factors, or proteins, in the coagulation (clotting) cascade. The term 'coagulation cascade' refers to a series of events, each dependent on the other, that stops bleeding through clot formation. Vitamin K-dependent γ-carboxylation of specific glutamic acid residues in those proteins makes it possible for them to bind calcium. Factors II (prothrombin), VII, IX, and X make up the core of the coagulation cascade. Protein Z appears to enhance the action of thrombin (the activated form of prothrombin) by promoting its association with phospholipids in cell membranes. Protein C and protein S are anticoagulant proteins that provide control and balance in the coagulation cascade; protein Z also has an anticoagulatory function. Control mechanisms for the coagulation cascade exist since uncontrolled clotting may be as life threatening as uncontrolled bleeding. Vitamin K-dependent coagulation factors are synthesized in the liver. Consequently, severe liver disease results in lower blood levels of vitamin K-dependent clotting factors and an increased risk for uncontrolled bleeding (hemorrhage) (8).

Oral anticoagulant therapy with vitamin K antagonists

Some people are at increased risk of forming clots, which could block the flow of blood in arteries of the heart, brain, or lungs, resulting in myocardial infarction (heart attack), stroke, or pulmonary embolism, respectively. Abnormal clotting is not related to excessive vitamin K intake, and there is no known toxicity associated with vitamin K_1 or vitamin K_2 (see Toxicity). Some oral anticoagulants, such as warfarin (Jantoven, formerly known as Coumadin), inhibit coagulation by antagonizing the action of vitamin K. Warfarin prevents the recycling of vitamin K by blocking VKOR activity, thus creating a functional vitamin K deficiency (**Figure 2**). Inadequate γ-carboxylation of vitamin K-dependent coagulation proteins interferes with the coagulation cascade, which inhibits blood clot formation. Large quantities of dietary or supplemental vitamin K can overcome the anticoagulant effect of vitamin K antagonists; thus, patients taking these drugs are cautioned against consuming very large or highly variable quantities of vitamin K (see Drug interactions). Experts now advise a reasonably constant dietary intake of vitamin K that meets current dietary recommendations (90-120 μg/day) for patients taking vitamin K antagonists like warfarin (9, 10).

Skeletal formation and prevention of soft tissue calcification

Vitamin K-dependent γ-carboxylation is essential to several bone-related proteins, including osteocalcin, anticoagulation factor protein S, matrix γ-carboxylated glutamate (Gla) protein (MGP), Gla-rich protein (GRP), and periostin (originally called osteoblast-specific factor-2). Osteocalcin (also known as bone Gla protein) is synthesized by osteoblasts (bone-forming cells); the synthesis of osteocalcin is regulated by the active form of vitamin D, 1,25-dihydroxyvitamin D (calcitriol). The calcium-binding capacity of osteocalcin requires vitamin K-dependent γ-carboxylation of three glutamic acid residues. Although its function in bone mineralization is not fully understood, osteocalcin is required for the growth and maturation of calcium hydroxyapatite crystals (see Osteoporosis) (11).

Protein S appears to play a role in the breakdown of bone mediated by osteoclasts. Individuals with inherited protein S deficiency suffer complications related to increased blood clotting, as well as osteonecrosis (12, 13). Protein S can bind and activate receptors of the TAM family that are involved in phagocytosis. Mutations in TAM receptors can result in visual impairment, defective spermatogenesis, autoimmune disorders, and platelet disorders (14).

MGP has been found in cartilage, bone, and soft tissue, including blood vessel walls, where it is synthesized and secreted by vascular smooth muscle cells. MGP is involved in the inhibition of calcification at various sites, including cartilage, vessel wall, skin elastic fibers, and the trabecular meshwork in the eye (see Vascular calcification) (15, 16). Moreover, several VKDPs, including MGP, have been associated with calcification sites in arteries, skin, kidneys, and eyes in certain inherited conditions, such as pseudoxanthoma elasticum and beta-thalassemia (17, 18).

The vitamin K-dependent proteins, GRP and periostin, are also synthesized in bone tissue, but their roles in bone metabolism are still unclear (19, 20). Expressed in normal human skin and vascular tissues, GRP has been colocalized with abnormal mineral deposits in the extracellular matrix in calcified arteries and calcified skin lesions (21). Expressed in most connective tissues, including skin and bone, periostin was initially associated with cell adhesion and migration. This VKDP also appears to promote angiogenesis (formation of new blood vessels) during cardiac valve degeneration and tumor growth (22, 23).

Current research suggests that reduced γ-glutamylcarboxylase activity and/or lower vitamin K bioavailability may impair the activity of VKDPs and contribute to bone mineralization defects and abnormal soft tissue calcification (see Disease Prevention) (24).

Regulation of cellular functions

Growth arrest-specific gene 6 protein (Gas6) is a vitamin K-dependent protein that was identified in 1993. It has been found throughout the nervous system, as well in the heart, lungs, stomach, kidneys, and cartilage. Identified as a ligand of the TAM family of transmembrane tyrosine kinase receptors, Gas6 appears to be a cellular growth regulation factor with cell-signaling activities. Gas6 has been involved in diverse cellular functions, including phagocytosis, cell adhesion, cell proliferation, and protection against apoptosis (5). It may also play important roles in the developing and aging nervous system (reviewed in 25). Further, Gas6 appears to regulate platelet signaling and vascular hemostasis (26). Expressed in most tissues and involved in many cellular functions, Gas6 has also been linked to several pathological conditions, including clot formation (thrombogenesis), atherosclerosis, chronic inflammation, and cancer growth (27-29).

Deficiency

Overt vitamin K deficiency results in impaired blood clotting, usually demonstrated by laboratory tests that measure clotting time. Symptoms include easy bruising and bleeding that may be manifested as nosebleeds, bleeding gums, blood in the urine, blood in the stool, tarry black stools, or extremely heavy menstrual bleeding. In infants, vitamin K deficiency may result in life-threatening bleeding within the skull (intracranial hemorrhage) (8).

Multiple biomarkers of vitamin K status exist (reviewed in 30), but only impaired blood coagulation is used as a measure of clinical vitamin K deficiency.

Adults

Vitamin K deficiency is uncommon in healthy adults for a number of reasons: (1) vitamin K is widespread in foods (see Food sources); (2) the vitamin K cycle conserves vitamin K (see Vitamin K oxidation-reduction cycle); and (3) bacteria that normally inhabit the large intestine synthesize menaquinones (vitamin K_2), although it is unclear whether significant amounts are absorbed and utilized (see Food sources). Adults at risk for vitamin K deficiency include those taking vitamin K antagonists and individuals with significant liver damage or disease (8). Additionally, individuals with fat malabsorption disorders, including inflammatory bowel disease and cystic fibrosis, may be at increased risk of vitamin K deficiency (31-34).

Infants

Newborn babies who are exclusively breast-fed are at increased risk for vitamin K deficiency because human milk is relatively low in vitamin K compared to formula. Newborn infants, in general, have low vitamin K status for the following reasons: (1) vitamin K transport across the placental barrier is limited; (2) liver storage of vitamin K is very low; (3) the vitamin K cycle may not be fully functional in newborns, especially premature infants; (4) the vitamin K content of breast milk is low, and immature gut flora (5, 35). Infants whose mothers are on anticonvulsant medication to prevent seizures are also at risk for vitamin K deficiency. Vitamin K deficiency in newborns may result in a bleeding disorder called vitamin K deficiency bleeding (VKDB) of the newborn (reviewed in 36). Because VKDB is life threatening and easily prevented, the American Academy of Pediatrics and a number of similar international organizations recommend that an intramuscular dose of phylloquinone (vitamin K_1) be administered to all newborns shortly after birth (reviewed in 37).

Controversies around vitamin K administration to newborns

Vitamin K and childhood leukemia: In the early 1990s, two retrospective studies were published suggesting a possible association between phylloquinone injections in newborns and the development of childhood leukemia and other forms of childhood cancer. However, two large retrospective studies in the US and Sweden, which reviewed the medical records of 54,000 and 1.3 million children, respectively, found no evidence of a relationship between childhood cancers and phylloquinone injections at birth (38, 39). Moreover, a pooled analysis of six case-control studies, including 2,431 children diagnosed with childhood cancer and 6,338 cancer-free children, found no evidence that phylloquinone injections for newborns increased the risk of childhood leukemia (40). In a policy statement, the American Academy of Pediatrics recommended that routine vitamin K prophylaxis for newborns be continued because VKDB is life threatening and the risks of cancer are unproven and unlikely (41). In the last decade, physicians have reported a rise in late-onset cases of VKDB due to an increasing trend of parental omission or refusal of newborn vitamin K prophylaxis (42, 43).

Lower doses of vitamin K_1 for premature infants: The results of two studies of vitamin K levels in premature infants suggest that the standard initial dose of phylloquinone (vitamin K_1) for full-term infants (1.0 mg) may be too high for premature infants (44, 45). These findings have led some experts to suggest the use of an initial phylloquinone dose of 0.3 mg/kg for infants with birth weights of less than 1,000 g (2 lbs, 3 oz), and an initial phylloquinone dose of 0.5 mg would probably prevent hemorrhagic disease in newborns (44). Yet, additional studies are needed to determine the best vitamin K prophylaxis in premature infants (46).

The Adequate Intake (AI)

In 2001, the US Food and Nutrition Board (FNB) of the Institute of Medicine (now the National Academy of Medicine) established the adequate intake (AI) level for vitamin K based on phylloquinone intake levels in healthy individuals (**Table 1**). The AI for infants was based on estimated intake of vitamin K from breast milk (47). The FNB did not consider menaquinone intakes; data on menaquinone consumption are limited (48).

Table 1. Adequate Intake (AI) for Vitamin K

Life Stage	Age	Males (μg/day)	Females (μg/day)
Infants	0-6 months	2.0	2.0
Infants	7-12 months	2.5	2.5
Children	1-3 years	30	30
Children	4-8 years	55	55
Children	9-13 years	60	60
Adolescents	14-18 years	75	75
Adults	19 years and older	120	90
Pregnancy	18 years and younger	-	75
Pregnancy	19 years and older	-	90
Breast-feeding	18 years and younger	-	75
Breast-feeding	19 years and older	-	90

Disease Prevention

Osteoporosis

The discovery of vitamin K-dependent proteins in bone has led to research on the role of vitamin K in maintaining bone health.

Vitamin K and bone health: observational studies

Vitamin K_1: Observational studies have found a relationship between phylloquinone (vitamin K_1) and age-related bone loss (osteoporosis). The Nurses' Health Study followed more than 72,000 women for 10 years. In an analysis of this cohort, women whose phylloquinone intakes were lower than 109 micrograms/day (μg/day) had a 30% higher risk for hip fracture compared to women with intakes equal to or above 109 μg/day (49). Another prospective study in over 800 elderly men and women, followed in the Framingham Heart Study for seven years, found that participants with dietary vitamin K intakes in the highest quartile (median, 254 μg/day) had a 65% lower risk of hip fracture than those with intakes in the lowest quartile (median, 56 μg/day) (50). Osteoporotic fractures are often linked to a reduction in bone mineralization. Yet, the investigators found no association between dietary phylloquinone intake and bone mineral density (BMD) in the Framingham subjects (50). While other studies failed to observe associations between dietary phylloquinone intake and measures of bone strength, BMD, or fracture incidence (51, 52), the cross-sectional study of a cohort of 3,199 middle-aged women found that subjects in the highest quartile of dietary phylloquinone intake had significantly greater hip and lumbar spine BMD than those in the lowest quartile (162 μg/day vs. 59 μg/day) (53). Moreover, cross-sectional and case-control studies have reported associations between higher phylloquinone intakes and lower incidence of hip fracture (54, 55).

However, because green leafy vegetables are the primary dietary source of phylloquinone and because they are usually part of a balanced diet, high phylloquinone consumption may simply be an indicator of healthy eating habits, which may — rather than phylloquinone itself — account for all or part of the association reported in observational studies (56).

The few studies that measured plasma phylloquinone generally found that higher circulating levels were associated with lower fracture risk (15, 57, 58). For example, the incidence of vertebral fractures was inversely correlated with lumbar BMD and plasma phylloquinone in a four-year prospective study that included 379 Japanese women ages 30-88 years (57). Yet, observational studies are not designed to making causal inferences, and only randomized controlled trials can evaluate whether phylloquinone may have beneficial effects on bone health (see Vitamin K supplementation studies and osteoporosis).

Vitamin K_2: There are few studies on associations between menaquinones (vitamin K_2) and bone health, perhaps because of the limited number of dietary sources of menaquinone-4 (MK-4), the main form of vitamin K_2 present in Western diets. The Japanese food natto, made of cooked soybeans fermented by *Bacillus subtilis natto*, is rich in MK-7. In a prospective cohort study that followed 944 Japanese women (ages 20-79 years), total hip BMD at baseline was positively associated with natto intake in postmenopausal women (59). During the three-year follow-up period, the rate of BMD loss at the femoral neck was significantly lower in women consuming natto (>200 μg/day of MK-7) compared to non-consumers. No association was found between natto intake and BMD in premenopausal women (59).

Total hip and femoral neck BMD was also reportedly higher in nearly 2,000 Japanese men aged 65 years and older who regularly consumed at least of one pack per day of natto (≥350 μg/day of MK-7) compared to those consuming less than one pack per week (<50 μg/day of MK-7) (60). Yet, increasing natto consumption also maximizes the intake of other dietary compounds (e.g., soy isoflavones) that have potential benefits for skeletal health; thus, there is need to find reliable measures of vitamin K status. To date, observational studies have failed to unequivocally support an association between circulating menaquinone (MK-7 and MK-4) levels and fracture risk (15, 61).

A meta-analysis that pooled the results of four prospective cohort studies and one nested case-control study found higher total dietary vitamin K intakes to be associated with a lower risk of total fracture (RR, 0.78; 95% CI: 0.56, 0.99) (62). In a recent Japanese cohort study not included in this meta-analysis (i.e., the Murakami Cohort Study), a protective association of dietary vitamin K intake was seen for vertebral fractures (p=0.005); vitamin K intake was not associated with total fracture in women or with either vertebral or total fracture in men (63).

Biomarker of vitamin K status and bone health

Total circulating levels of the bone protein, osteocalcin (OC), have been shown to be sensitive markers of bone formation. Several hormones and growth factors, including vitamin D but not vitamin K, regulate osteocalcin synthesis by osteoblasts. However, vitamin K is an essential cofactor for the γ-carboxylation of three glutamic acid residues in osteocalcin. Undercarboxylation of osteocalcin in human bone and serum has been linked to poor vitamin K status. The degree of osteocalcin γ-carboxylation is responsive to vitamin K nutritional interventions, and thus is used as a relative indicator of vitamin K status (11).

Circulating levels of uncarboxylated osteocalcin (ucOC) were found to be higher in postmenopausal women than premenopausal women and markedly higher in women over the age of 70. Also, high ratios of ucOC to total OC (ucOC/OC) appear to be predictive of hip fracture risk in elderly women (64, 65). Although vitamin K deficiency would seem the most likely cause of elevated blood ucOC/OC ratio, some investigators have documented an inverse relationship between biochemical measures of vitamin D nutritional status and ucOC levels, as well as a significant lowering of ucOC/OC ratio by vitamin D supplementation (66). It has been suggested that increased circulating ucOC/OC ratio could reflect a poor overall nutritional status that would include vitamin D inadequacy, which would explain the above-mentioned observations (67). However, in several randomized, placebo-controlled intervention studies conducted in young girls (67, 68) and postmenopausal women (69), vitamin D supplementation failed to decrease ucOC/OC ratios or show any additive effect on ucOC/OC lowering by supplemental vitamin K.

Vitamin K supplementation studies and osteoporosis

Vitamin K_1 supplementation: The review of five randomized clinical trials that assessed the effect of phylloquinone (vitamin K_1) supplementation on hip BMD using doses ranging from 200 μg/day to 5,000 μg/day for durations of 12 to 36 months found little promising benefit for bone health (15). Although supplementation with phylloquinone decreased ucOC levels in all five studies, only one study reported an effect of supplemental phylloquinone on BMD (70). In this study, 150 postmenopausal women were randomized to receive a placebo, minerals (500 mg/day of calcium, 150 mg/day of magnesium, and 10 mg/day of zinc) plus vitamin D (320 IU/day), or minerals, vitamin D, and phylloquinone (1,000 μg/day). The rate of BMD loss at the femoral neck, but not at the lumbar spine, was significantly lower in subjects with supplemental phylloquinone compared to the other two groups. Thus, evidence of a putative benefit of phylloquinone on bone health in older adults is considered weak. None of the studies were designed to assess the effect of phylloquinone on osteoporotic-related fractures. Further investigation may seek to evaluate whether phylloquinone supplementation could improve skeletal health in subjects at high-risk for vitamin K inadequacy (e.g., individuals with malabsorption syndromes or cystic fibrosis).

Vitamin K_2 supplementation: Pharmacological doses of menaquinone-4 (MK-4; brand name, menatetrenone) are currently used in Japan in the treatment of osteoporosis (71). Accordingly, most intervention trials investigating the effect of high-dose MK-4 on bone loss have been conducted in Japanese postmenopausal women. In a three-year placebo-controlled trial among postmenopausal women with osteopenia, adding a MK-7 supplement (375 μg/day) to combined calcium-vitamin D supplementation did not affect BMD or other bone health parameters despite reductions in serum ucOC (72). At present, the potential role for supplemental menaquinones on bone health still needs to be established in large, randomized, and well-controlled trials.

A 2019 systematic review and meta-analysis of clinical trials in postmenopausal women or women with osteoporosis found vitamin K supplementation — of any form — lowered risk of clinical fracture compared to controls (OR, 0.72; 95% CI, 0.55-0.95; 9 trials varying from 6 months to 2 years: 3 using phylloquinone, 5 using MK-4, and 1 using MK-7) (73). However, no benefit of vitamin K supplementation was seen for vertebral fractures (7 trials) or BMD (22 trials). The authors of this meta-analysis noted that the high heterogeneity of the included trials (i.e., form and dose of vitamin K, use of other supplements and drugs by participants, and treatment length) makes it difficult to inform clinical recommendations (73).

Vitamin K antagonists and bone health

Certain oral anticoagulants, such as warfarin, are known to be antagonists of vitamin K (see Coagulation). Few studies have examined chronic use of warfarin and risk of fracture in older women. One study reported no association between long-term warfarin treatment and fracture risk (74), while another one found a significantly higher risk of rib and vertebral fractures in warfarin users compared to nonusers (75). Additionally, a study in elderly patients with atrial fibrillation reported that long-term warfarin treatment was associated with a significantly higher risk of osteoporotic fracture in men but not in women (76). A meta-analysis of the results of 11 published studies found that oral anticoagulation therapy was associated with a very modest reduction in BMD at the wrist and no change in BMD at the hip or spine (77). The development of new anticoagulants that do not block vitamin K recycling may offer a safer alternative to the use of vitamin K antagonists (78).

Cardiovascular disease

Observational studies examining vitamin K intake in relation to cardiovascular-related mortality have found conflicting results (48). An inverse relationship between vitamin K intake and mortality was reported in a US national survey (NHANES III) of 3,401 participants (79). Adequate vs. inadequate vitamin K intakes (based on sex-specific AI: 90 μg/day for women and 120 μg/day for men) were associated with a 22% lower risk of cardiovascular disease (CVD)-related mortality and a 15% lower risk of all-cause mortality. The report also indicated that, while over two-thirds of individuals with chronic kidney disease had vitamin K intakes below the AI, the risk of CVD mortality was 41% lower in those with adequate compared to suboptimal intakes (79). However, higher vitamin K intakes were not associated with lower CVD mortality in a prospective study that followed 7,216 older adults at risk for developing CVD (80). This study associated higher intakes of phylloquinone, but not of menaquinones, with lower risk of all-cause mortality. More recently, in a prospective study that followed a cohort of 33,289 Dutch men and women for an average of 16.8 years (the EPIC-Netherlands), neither phylloquinone intake nor menaquinone intake at baseline was associated with mortality from cardiovascular disease, coronary heart disease, stroke, or all causes (81). Yet, a prospective study of 56,048 men and women participating in the Danish Diet, Cancer, and Health cohort reported higher phylloquinone intakes to be associated with lower risks of both cardiovascular disease-related mortality and all-cause mortality (82). Moreover, a few studies have examined the association of fasting circulating phylloquinone with cardiovascular-related or all-cause mortality. In a recent meta-analysis of individual participant data from three prospective cohort studies (the Multi-Ethnic Study of Atherosclerosis; the Health, Aging, and Body Composition Study, and the Framingham Offspring Study), a blood phylloquinone concentration less than or equal to 0.5 nmol/L (n=1,081) was associated with a 19% higher risk of all-cause mortality compared to a blood concentration >1.0 nmol/L (n=1,698; 83). This analysis did not find circulating phylloquinone to be linked with incident cardiovascular disease (83).

Observational studies offer limited support of an inverse relationship between phylloquinone intake and risk of incident cardiovascular disease, despite high intakes being sometimes regarded as a marker of healthy dietary habits associated with low cardiovascular risk (reviewed in 84). A prospective cohort study of 16,057 Dutch women (ages 49-70 years), followed for a mean period of 8.1 years, found a 9% reduction in risk for coronary heart disease (CHD) per each incremental 10 μg/day increase in menaquinone intake (85). In another earlier Dutch study that examined 4,807 healthy men and women 55 years and older, participants in the highest tertile of menaquinone intake (>32.7 μg/day) had a 41% lower risk of incident CHD and a 26% lower risk of all-cause mortality than those in the lowest tertile (<21.6 μg/day) (86). In addition, menaquinone intake was found to be inversely associated with aortic calcification, a major risk factor for CVD (86). A smaller prospective study among 2,987 Norwegian adults, followed for an average of 10.8 years, reported higher dietary intakes of vitamin K_2, but not of vitamin K_1, were associated with a lower risk of CHD (87). While these data are interesting, it is important to note that vitamin K_2 may solely be a marker of a heart-healthy diet and might not itself be cardioprotective. Most recently, the prospective Danish Diet, Cancer, and Health Study followed 53,372 older adults for an average of 21 years, finding both phylloquinone and menaquinone intake at baseline to be inversely associated with hospitalizations due to atherosclerotic cardiovascular events, including ischemic heart disease, ischemic stroke, and peripheral arterial disease (88).

Large-scale supplementation trials are needed to determine whether vitamin K_1 or vitamin K_2 reduces the risk of CHD or cardiovascular-related events like myocardial infarction or stroke.

Vascular calcification

One of the hallmarks of cardiovascular disease is the presence of atherosclerotic plaques in arterial walls. Plaque rupture that causes blood clot formation (thrombogenesis) is the usual cause of a myocardial infarction (heart attack) or stroke. While calcification of the plaques occurs as the atherosclerosis progresses, it is unclear whether calcification increases plaque instability and could predict risk of rupture and thrombogenesis (89). However, calcification may be predictive of future cardiovascular events, especially in those with chronic kidney disease (90). A meta-analysis of 30 prospective cohort studies, including a total of 218,080 participants, found that the presence of vascular calcification was associated with an overall three- to four-fold increased risk of cardiovascular events and mortality (91). An early population-based study of postmenopausal women (ages, 60-79 years) observed that the younger women (60-69 years) with aortic calcifications had lower vitamin K intakes than those without aortic calcifications, but this was not true for older women (70-79 years) (92). A prospective cohort study in 807 men and women, 39-45 years of age, did not find any correlation between dietary phylloquinone intake and coronary artery calcification, as measured non-invasively by computed tomography (93). Additionally, neither phylloquinone nor menaquinone intake was associated with calcification of breast arteries in a cross-sectional study of 1,689 women ages 49-70 years (94). However, in another cross-sectional study, the upper *vs*. lowest quartile of menaquinone (MK-4 to MK-10) intake (median intakes, 48.5 μg/day vs. 18 μg/day) was found to be associated with a 20% reduced prevalence of coronary artery calcification in 564 postmenopausal women (95).

Research has uncovered possible mechanisms by which vitamin K may inhibit mineralization (calcification) of vessels while promoting bone mineralization. The potential mechanisms, although not yet fully understood, implicate vitamin K-dependent proteins, including matrix Gla protein (MGP), Gla-rich protein (GRP), and Gas6 (96-98). Secreted by various cell types, such as vascular smooth muscle cells (VSMCs) in arterial vessel walls, MGP appears to be important for the prevention of calcification of soft tissues, including cartilage, vasculature, skin, and trabecular meshwork cells in the eye (15, 99). In MGP knockout mice, conversion of VSMCs into bone-like cells and extensive vessel calcification results in large vessel rupture and premature death. In humans, defective *MGP* gene has been linked to Keutel syndrome, a rare inherited condition characterized in particular by abnormal cartilage calcification and pulmonary artery stenosis (narrowing). Calcification prevention by MGP involved several mechanisms, including the binding to calcium crystals and the inhibition of proteins (bone morphogenic proteins; BMPs) known to promote ectopic bone formation (reviewed in 100).

Calcium-binding activity of MGP is regulated by two types of modifications (known as post-translational modifications since they take place after protein synthesis): the vitamin K-dependent carboxylation of up to five Glu residues and the phosphorylation of serine residues. A variation in the sequence (polymorphism) of the gene for MGP leading to a threonine-to-alanine transition in one of the five Gla domains of the protein may possibly prevent carboxylation and elicit a change in MGP ability to bind calcium. This polymorphism, known as *MGP*Thr83Ala, has been associated with the progression of coronary artery calcification over a mean period of 10.6 years in a community-based prospective study that followed 605 middle-aged men and women (101). This association was only observed among participants without detectable calcification at baseline and not in those who had baseline calcification (101). Interestingly, *MGP*Thr83Ala was also associated with higher risk of myocardial infarction and femoral artery calcification in carriers of the genotype (102).

Additionally, a small study initially found that, while undercarboxylated MGP (ucMGP) was absent from the innermost lining of the carotid arteries in healthy subjects, the majority of MGP in the carotid arterial lining of patients with atherosclerosis was undercarboxylated (103). In another study that examined the association between circulating MGP and incident cardiovascular events in 577 older men and women followed for a mean period of 5.6 years, the risk of cardiovascular disease (i.e., coronary artery disease, peripheral arterial disease, and cerebrovascular disease) was two- to three-fold greater in subjects in the highest *vs*. lowest tertile of plasma dephosphorylated and undercarboxylated MGP (dp-ucMGP) (104). The results of another prospective study suggested that circulating dp-ucMGP may be predictive of mortality risk in subjects with overt vascular disease (105). Indeed, the risk of cardiovascular-related and all-cause mortality was found to be nearly doubled in subjects with coronary artery disease or stroke in the highest *vs*. lowest quartile of dp-ucMGP concentrations (105).

Because suboptimal vitamin K nutritional status may limit carboxylation and result in biologically inactive ucMGP, it has been speculated that vitamin K supplementation may protect against vascular calcification. A three-year, double-blind, controlled trial investigated the potential effect of vitamin K on the progression of coronary calcification in 401 older, community-dwelling adults (ages, 60-80 years) free of cardiovascular disease at baseline (106). The participants were randomized to receive a daily multivitamin plus calcium and vitamin D with or without 500 mg of phylloquinone. Using measurements of coronary artery calcification at baseline and follow up, it was found that phylloquinone supplementation was able to limit the progression of vascular calcification and reduce plasma dp-ucMGP compared to control (106, 107). Although circulating dp-ucMGP was correlated to various markers of vitamin K status, no association with measures of coronary artery calcification were found (107). Smaller trials in those at high risk for coronary artery disease (108) or with existing aortic valve calcification (109), type 2 diabetes mellitus (110), or kidney disease (111, 112) have reported no benefit of vitamin K_2 supplementation on progression of vascular calcification. A meta-analysis of controlled clinical trials found that vitamin K supplementation reduced dp-ucMGP (7 trials), reduced ucOC (4 trials), and decreased progression of vascular calcification (3 trials) (113). Yet, the authors emphasize that any conclusions from their pooled analysis are limited by the high heterogeneity of the trials with respect to the form and dose of vitamin K utilized, as well as the assays that assessed vascular calcification (113).

Thus, further investigations are necessary to examine the role of other vitamin K-dependent proteins (e.g., GRP, periostin, Gas6) in human atherosclerotic plaque calcification and to evaluate the effect of supplemental vitamin K on the progression of vascular calcification and risk of cardiovascular disease.

Vitamin K antagonists and vascular calcification

Several cross-sectional studies have reported increased vascular calcium scores (a means to quantify vascular calcification) in chronic users of vitamin K antagonists compared to nonusers (reviewed in 114). Warfarin therapy has also been associated with higher circulating concentrations of dp-ucMGP in a prospective study that examined vascular calcification in subjects with cardiovascular disease (105). Newly developed direct inhibitors of coagulation factors that do not interfere with VKDP activity may be more suitable than vitamin K antagonists, especially with regards to vascular calcification (114).

Osteoarthritis

Osteoarthritis, a degenerative joint condition that affects more than 32 million US adults (115), is characterized by the breakdown of articular cartilage (i.e., cartilage within the joint). Because several vitamin K-dependent proteins are present in cartilage and in bone (116), vitamin K inadequacy may have a role in the development of osteoarthritis. A few observational studies have investigated a possible link between vitamin K intake or status and osteoarthritis. A cross-sectional study among 719 Japanese older adults found dietary intake of vitamin K to be inversely associated with knee osteoarthritis (117). In the Framingham Offspring Study (n=672; mean age, 66 years), higher plasma concentrations of phylloquinone were associated with a lower risk of hand, but not knee, osteoarthritis (118). A longitudinal study of 1,180 US adults (mean age, 62 years) found that low plasma concentrations of phylloquinone (≤0.5 nM) at baseline — indicative of a subclinical vitamin K deficiency — were associated with a 56% increase in risk of knee osteoarthritis after 30 months compared to those with higher plasma concentrations (119). In a more recent longitudinal study among 523 older US adults participating in the Health, Aging, and Body Composition Study, those with extremely low plasma concentrations of phylloquinone (<0.2 nM) at baseline had increased progression of knee osteoarthritis over three years, assessed by MRI of articular cartilage and the meniscus; those with higher plasma concentrations experienced no significant progression of knee osteoarthritis (120). Moreover, recent studies have associated use of the vitamin K antagonist drugs with higher risks of osteoarthritis (121) and joint replacement (121) of the knee and hip compared to nonusers.

While these observational data are interesting, randomized controlled trials are needed to determine whether vitamin K supplementation in those with low vitamin K status might help prevent or treat osteoarthritis. In an ancillary study of a double-blind, controlled trial examining the effects of vitamin K supplementation on bone loss and vascular calcification in older adults, no effects of phylloquinone supplementation (500 μg/day) were found on incidence of hand osteoarthritis after three years (122). Study participants were not screened for vitamin K status, and in a subgroup analysis, those with serum phylloquinone ≤1 nM at baseline that reached >1 nM at year 3 had less joint deterioration. These data infer that only those individuals with low vitamin K status benefit from vitamin K supplementation. Unfortunately, no measures were available for knee osteoarthritis, and it is well established that hand and knee osteoarthritis represent different phenotypes. Additional clinical trials that specifically examine the effect of vitamin K supplementation on osteoarthritis development are needed, especially in those with inadequate vitamin K status.

Sources

A US national survey, NHANES 2011-2012, found that average dietary intakes of vitamin K (all forms) vary greatly among individuals, with values ranging from 80 to 195 μg/day of phylloquinone for men and 78 to 223 μg/day of phylloquinone for women (123). Mean intakes for both men and women were 117 μg/day of phylloquinone; however, 57% of men and 37% of women did not meet the Adequate Intake (AI) level (123).

Food sources

Vitamin K_1

Phylloquinone (vitamin K_1) is the major dietary form of vitamin K in most diets. Green leafy vegetables and some plant oils (soybean, canola, olive, and cottonseed) are major contributors of dietary vitamin K. Mixed dishes have also been found to significantly contribute to vitamin K intake in the US (123). However, phylloquinone bioavailability from green vegetables is lower than from oil or supplements. Also, the phylloquinone content of green vegetables depends on their content in chlorophyll (green pigment), so that outer leaves have more phylloquinone than inner leaves. The efficiency of phylloquinone intestinal absorption varies among plant sources and is increased with the addition of a fat source to a meal. Finally, the hydrogenation of vegetable oils may decrease the absorption and biological effect of dietary phylloquinone (reviewed in 2, 9). If you wish to check foods for their nutrient content, including phylloquinone, search USDA's FoodData Central. A number of phylloquinone-rich foods are listed in **Table 2**, with their content in phylloquinone expressed in micrograms (μg).

Table 2. Some Food Sources of Phylloquinone

Food	Serving	Phylloquinone (μg)
Kale, frozen, boiled	1 cup	493
Chard, raw	1 cup	299
Parsley, raw	¼ cup	246
Broccoli, cooked	1 cup	220
Spinach, raw	1 cup	121
Watercress, raw	1 cup	85
Cabbage, green, raw	1 cup	68
Romaine lettuce, raw	1 cup	44
Soybean oil	1 Tablespoon	26
Canola oil	1 Tablespoon	10
Olive oil	1 Tablespoon	8
Cottonseed oil	1 Tablespoon	3

Vitamin K_2

Menaquinones (vitamin K_2) are primarily of microbial origins and thus commonly found in fermented foods, such as cheese, curds, and natto (fermented soybeans) (124, 125). MK-4 is the only menaquinone that is not produced by bacteria. MK-4 is formed from menadione (a synthetic form of vitamin K) found in animal feeds or is converted in a tissue-specific way from multiple dietary forms of vitamin K, including phylloquinone and various menaquinones (4, 126). Menaquinone-4 is found in dairy products, including milk, and in some meats (125). Longer chain menaquinones are found in limited fermented food products. The Japanese fermented soybean-based, natto, is rich in MK-7 (998 μg/100 g) and also contains MK-8 (84 μg/100 g). Some cheeses contain MK-8 and MK-9 (2, 125). Additionally, animal livers are a source of long-chain menaquinones (MK-7 to MK-13) (9).

Food composition databases, including USDA's FoodData Central, have limited data on menaquinone content in foods. Thus, menaquinone contribution to total vitamin K intakes is difficult to estimate and likely to vary between populations with different food consumption practices (2, 125). Bacteria that normally colonize the large intestine (colon) can synthesize menaquinones. It was initially thought that up to 50% of the human vitamin K requirement might be met by bacterial synthesis. However, all forms of vitamin K are absorbed in the small intestine via a mechanism requiring bile salts, while most of the menaquinone production takes place in the colon where bile salts are lacking. Current research suggests that the contribution of bacterial synthesis to vitamin K status is much less than previously thought, although the exact contribution remains unclear (16, 127).

Supplements

In the US, both phylloquinone and menaquinones are available without a prescription in multivitamin, single-nutrient, or multiple-nutrient supplements in varying doses; vitamin K content of multivitamins typically range from 20 to 120 μg per tablet (128). The US Food and Drug Administration (FDA) has not authorized any health claims for any forms of vitamin K.

Safety

Toxicity

Although allergic reactions are possible, there is no known toxicity associated with high doses (dietary or supplemental) of the phylloquinone (vitamin K_1) or menaquinone (vitamin K_2) forms of vitamin K (47). The same is not true for synthetic menadione (vitamin K_3) and its derivatives. Menadione can interfere with the function of glutathione, one of the body's natural antioxidants, resulting in oxidative damage to cell membranes. Menadione given by injection has induced liver toxicity, jaundice, and hemolytic anemia (due to the rupture of red blood cells) in infants; therefore, menadione is no longer used for treatment of vitamin K deficiency (5). No tolerable upper intake level (UL) has been established for vitamin K (47).

Nutrient interactions

Large doses of vitamin A and vitamin E have been found to antagonize vitamin K (8). Excess vitamin A appears to interfere with vitamin K absorption, whereas vitamin E may inhibit vitamin K-dependent carboxylase activity and interfere with the coagulation cascade (129). One study in adults with normal coagulation status found that supplementation with 1,000 IU/day of vitamin E for 12 weeks decreased γ-carboxylation of prothrombin, a vitamin K-dependent protein (130). Individuals taking anticoagulatory drugs like warfarin and those who are vitamin K deficient should not take vitamin E supplements without close medical supervision because of the increased risk of hemorrhage (excessive bleeding) (131).

Drug interactions

The anticoagulant effect of vitamin K antagonists (e.g., warfarin) may be compromised by very high dietary or supplemental vitamin K intake. Moreover, daily phylloquinone supplements of up to 100 μg are considered safe for patients taking warfarin, but therapeutic anticoagulant stability may be undermined by daily doses of MK-7 as low as 10 to 20 μg (132). It is generally recommended that individuals using warfarin try to consume the AI for vitamin K (90-120 μg/day) and avoid large fluctuations in vitamin K intake that might interfere with the adjustment of their anticoagulant dose (9, 10, 133). The prescription of anti-vitamin K anticoagulants, anticonvulsants (e.g., phenytoin), and anti-tuberculosis drugs (e.g., rifampin and isoniazid) to pregnant or breast-feeding women may place the newborn at increased risk of vitamin K deficiency (134).

The drug amiodarone, used in the management of certain cardiac arrhythmias (irregular heartbeat), including atrial fibrillation, can enhance the anticoagulant effect of warfarin and thus increase the risk of hemorrhage (135, 136). Further, the use of cholesterol-lowering medications (like cholestyramine and colestipol), as well as orlistat, mineral oil, and the fat substitute, olestra, may interfere with fat absorption and affect the absorption of fat-soluble vitamins, including vitamin K (137).

Linus Pauling Institute Recommendation

It is not clear whether the AI for vitamin K is enough to optimize the γ-carboxylation of vitamin K-dependent proteins in bone (see Osteoporosis). To consume the amount of vitamin K associated with a decreased risk of hip fracture in the Framingham Heart Study (about 250 μg/day) (50), an individual would need to eat a little more than ½ cup of chopped broccoli or a large salad of mixed greens every day. Though the dietary intake of vitamin K required for optimal function of all vitamin K-dependent proteins is not yet known, the Linus Pauling Institute recommends taking a multivitamin/mineral supplement and eating at least one cup of dark-green leafy vegetables daily. Replacing dietary saturated fats like butter and cheese with monounsaturated fats found in olive oil and canola oil will increase dietary vitamin K intake and may decrease the risk of cardiovascular disease.

Older adults (>50 years)

Because older adults are at increased risk of osteoporosis and hip fracture, the above recommendation for a multivitamin/mineral supplement and at least one cup of dark green leafy vegetables daily is especially relevant.

Minerals

Español

Minerals are elements that originate in the Earth and cannot be made by living organisms. Plants obtain minerals from the soil, and most of the minerals in our diets come directly from plants or indirectly from animal sources. Minerals may also be present in the water we drink, but this varies with geographic locale. Minerals from plant sources may also vary from place to place, because soil mineral content varies geographically.

The information from the Linus Pauling Institute's Micronutrient Information Center on vitamins and minerals is now available in a book titled, *An Evidence-based Approach to Vitamins and Minerals: Health Benefits and Intake Recommendations*. The book can be purchased from the Linus Pauling Institute or Thieme Medical Publishers.

Summary

- Calcium is a major constituent of bones and teeth and also plays an essential role as second messenger in cell-signaling pathways. Circulating calcium concentrations are tightly controlled by the parathyroid hormone (PTH) and vitamin D at the expense of the skeleton when dietary calcium intakes are inadequate. *(More information)*
- The recommended dietary allowance (RDA) for calcium is 1,000 mg/day-1,200 mg/day for adults. *(More information)*
- The skeleton is a reserve of calcium drawn upon to maintain normal serum calcium in case of inadequate dietary calcium. Thus, calcium sufficiency is required to maximize the attainment of peak bone mass during growth and to limit the progressive demineralization of bones later in life, which leads to osteoporosis, bone fragility, and an increased risk of fractures. *(More information)*
- High concentrations of calcium and oxalate in the urine are major risk factors for the formation of calcium oxalate stones in the kidneys. Because dietary calcium intake has been inversely associated with stone occurrence, it is thought that adequate calcium consumption may reduce the absorption of dietary oxalate, thus reducing urinary oxalate and kidney stone formation. *(More information)*
- Data from observational studies and randomized controlled trials support calcium supplementation in reducing the risk of high blood pressure and preeclampsia in pregnant women. The World Health Organization advises that all pregnant women in areas of low calcium intake (i.e., low-income countries with intakes around 300 to 600 mg/day) be given supplemental calcium starting in the 20th week of pregnancy. *(More information)*
- Prospective cohort studies have reported an association between higher calcium intakes and lower risk of developing colorectal cancer; however, large clinical trials of calcium supplementation are needed. *(More information)*
- Current available data suggest that adequate calcium intakes may play a role in body weight regulation and have therapeutic benefits in the management of moderate-to-severe premenstrual symptoms. *(More information)*
- Adequate calcium intake is critical for maintaining a healthy skeleton. Calcium is found in a variety of foods, including dairy products, beans, and vegetables of the kale family. Yet, content and bioavailability vary among foods, and certain drugs are known to adversely affect calcium absorption. *(More information)*
- Hypercalcemia, a condition of abnormally high concentrations of calcium in blood, is usually due to malignancy or primary hyperparathyroidism. However, the use of large doses of supplemental calcium, together with absorbable alkali, increases the risk of hypercalcemia, especially in postmenopausal women. Often associated with gastrointestinal disturbances, hypercalcemia can be fatal if left untreated. *(More information)*
- High calcium intakes — either from dairy foods or from supplements — have been associated with increased risks of prostate cancer and cardiovascular events in some, but not all, observational and intervention studies. However, there is currently no evidence of such detrimental effects when people consume a total of 1,000 to 1,200 mg/day of calcium (diet and supplements combined), as recommended by the Food and Nutrition Board of the Institute of Medicine. *(More information)*

Calcium is the most abundant mineral in the human body. About 99% of the calcium in the body is found in bones and teeth, while the other 1% is found in the blood and soft tissue. Calcium concentrations in the blood and fluid surrounding the cells (extracellular fluid) must be maintained within a narrow concentration range for normal physiological functioning. The physiological functions of calcium are so vital to survival that the body will stimulate bone resorption (demineralization) to maintain normal blood calcium concentrations when calcium intake is inadequate. Thus, adequate intake of calcium is a critical factor in maintaining a healthy skeleton (1).

Function

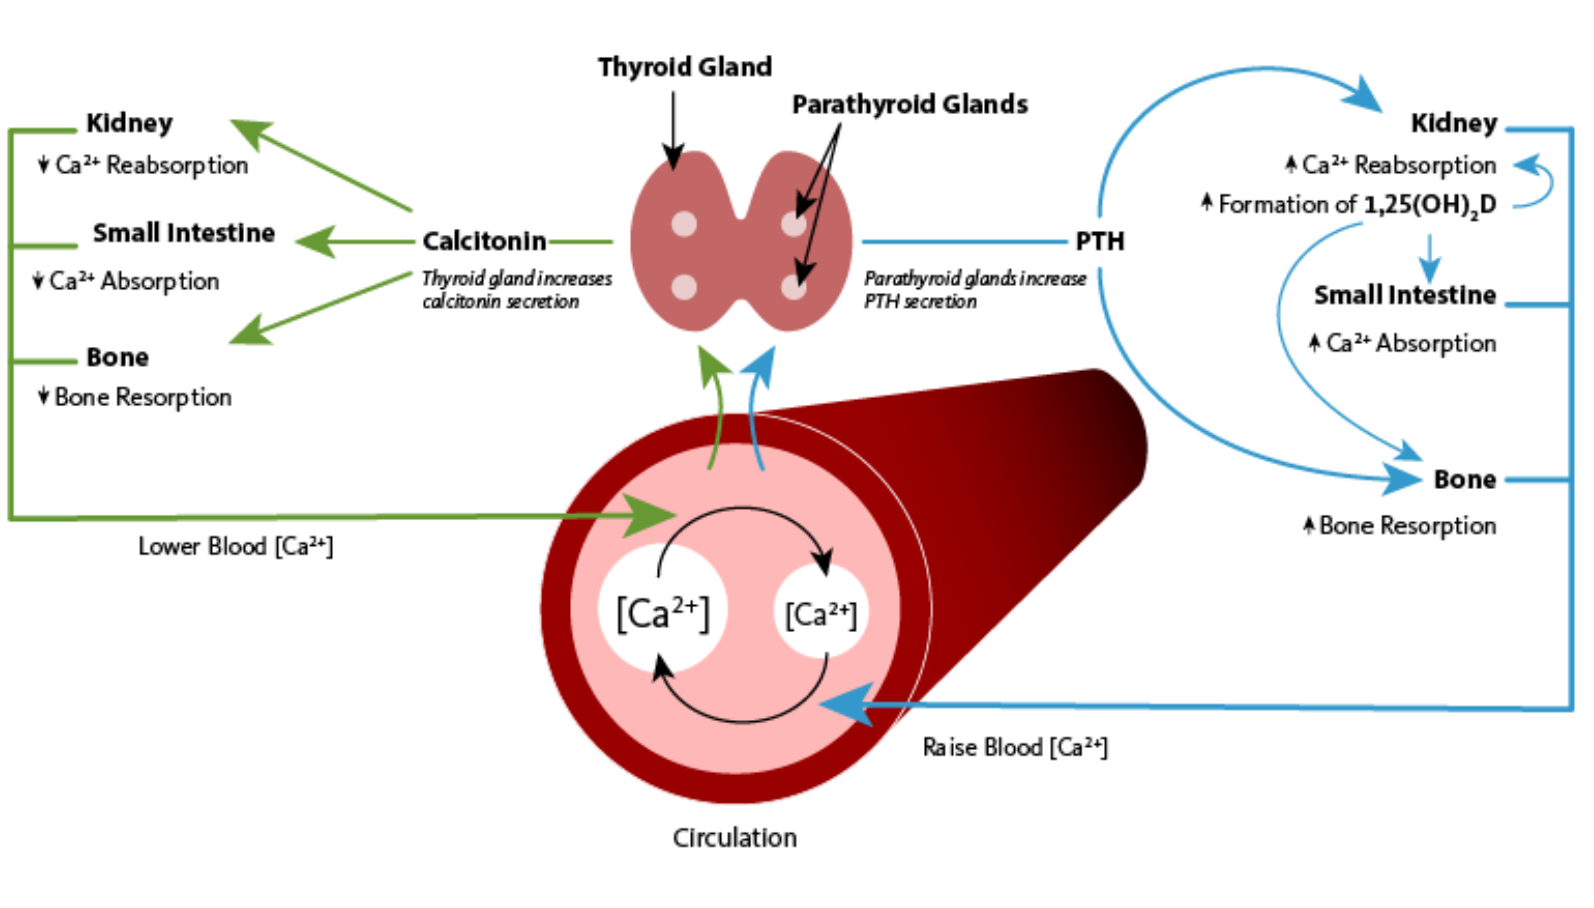
Structure

Calcium is a major structural element in bones and teeth. The mineral component of bone consists mainly of hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$ crystals, which contain large amounts of calcium, phosphorus, and oxygen. Bone is a dynamic tissue that is remodeled throughout life. Bone cells called osteoclasts begin the process of remodeling by dissolving or resorbing bone. Bone-forming cells called osteoblasts then synthesize new bone to replace the bone that was resorbed. During normal growth, bone formation exceeds bone resorption. Osteoporosis may result when bone resorption chronically exceeds formation (1).

Calcium homeostasis

Calcium concentrations in the blood and fluid that surround cells are tightly controlled in order to preserve normal physiological function. A slight drop in blood calcium concentration (e.g., in the case of inadequate calcium intake) is sensed by the parathyroid glands, resulting in their increased secretion of parathyroid hormone (PTH). In the kidneys, PTH stimulates the conversion of vitamin D into its active form (1,25-dihydroxyvitamin D; calcitriol), which rapidly decreases urinary excretion of calcium but increases urinary excretion of phosphorus. Elevations in PTH also stimulates bone resorption, resulting in the release of bone mineral (calcium and phosphate) — actions that also contribute to restoring serum calcium concentrations. Increased circulating 1,25-dihydroxyvitamin D also triggers intestinal absorption of both calcium and phosphorus. Like PTH, 1,25-dihydroxyvitamin D stimulates the release of calcium from bone by activating osteoclasts (bone-resorbing cells). When blood calcium rises to normal levels, the parathyroid glands stop secreting PTH. A slight increase in blood calcium concentration stimulates the production and secretion of the peptide hormone, calcitonin, by the thyroid gland. Calcitonin inhibits PTH secretion, decreases both bone resorption and intestinal calcium absorption, and increases urinary calcium excretion (**Figure 1**). Finally, acute changes in blood calcium concentrations do not seem to elicit the secretion of the phosphaturic hormone fibroblast growth factor 23 (FGF-23), which is produced by bone-forming cells (osteoblasts/osteocytes) in response to increases in phosphorus intake (see the article on Phosphorus) (2). While this complex system allows for rapid and tight control of blood calcium concentrations, it does so at the expense of the skeleton (1).

Figure 1. Calcium Homeostasis



[Figure 1 - Click to Enlarge]

Cell signaling

Calcium plays a role in mediating the constriction and relaxation of blood vessels (vasoconstriction and vasodilation), nerve impulse transmission, muscle contraction, and the secretion of hormones like insulin (1). Excitable cells, such as skeletal muscle and nerve cells, contain voltage-dependent calcium channels in their cell membranes that allow for rapid changes in calcium concentrations. For example, when a nerve impulse stimulates a muscle fiber to contract, calcium channels in the cell membrane open to allow calcium ions into the muscle cell. Within the cell, these calcium ions bind to activator proteins, which help release a flood of calcium ions from storage vesicles of the endoplasmic reticulum (ER) inside the cell. The binding of calcium to the protein troponin-c initiates a series of steps that lead to muscle contraction. The binding of calcium to the protein calmodulin activates enzymes that break down muscle glycogen to provide energy for muscle contraction. Upon completion of the action, calcium is pumped outside the cell or into the ER until the next activation (reviewed in 3).

Regulation of protein function

Calcium is necessary to stabilize a number of proteins, including enzymes, optimizing their activities. The binding of calcium ions is required for the activation of the seven "vitamin K-dependent" clotting factors in the coagulation cascade. The term, "coagulation cascade," refers to a series of events, each dependent on the other that stops bleeding through clot formation (see the article on Vitamin K).

Nutrient interactions

Vitamin D

Vitamin D is required for optimal calcium absorption (see Function or the article on Vitamin D). Several other nutrients (and non-nutrients) influence the retention of calcium by the body and may affect calcium nutritional status.

Sodium

Dietary sodium is a major determinant of urinary calcium loss (1). High-sodium intake results in increased loss of calcium in the urine, possibly due to competition between sodium and calcium for reabsorption in the kidneys or by an effect of sodium on parathyroid hormone (PTH) secretion. Every 1-gram (g) increment in sodium (2.5 g of sodium chloride; NaCl salt) excreted by the kidneys has been found to draw about 26.3 milligrams (mg) of calcium into the urine (1). A study conducted in adolescent girls reported that a high-salt diet had a greater effect on urinary sodium and calcium excretion in White compared to Black girls, suggesting differences among ethnic groups (4). In adult women, each extra gram of sodium consumed per day is projected to produce an additional rate of bone loss of 1% per year if all of the calcium loss comes from the skeleton.

A number of cross-sectional and intervention studies have suggested that high-sodium intakes are deleterious to bone health, especially in older women (5). A two-year longitudinal study in postmenopausal women found increased urinary sodium excretion (an indicator of increased sodium intake) to be associated with decreased bone mineral density (BMD) at the hip (6). Another study in 40 postmenopausal women found that adherence to a low-sodium diet (2 g/day) for six months was associated with significant reductions in sodium excretion, calcium excretion, and amino-terminal propeptide of type I collagen, a biomarker of bone resorption. Yet, these associations were only observed in women with elevated baseline urinary sodium excretions (7). Finally, in a randomized, placebo-controlled study in 60 postmenopausal women, potassium citrate supplementation has been found to prevent an increase in calcium excretion induced by the consumption of a high-sodium diet (≥5,000 mg/day of elemental sodium) for four weeks (8).

Protein

Increasing dietary protein intake enhances intestinal calcium absorption, as well as urinary calcium excretion (9). The RDA for protein is 46 grams (g)/day for adult women and 56 g/day for adult men; however, the average intake of protein in the US tends to be higher (about 70 g/day in adult women and over 100 g per day in adult men) (10). It was initially thought that high-protein diets may result in a negative calcium balance (when the sum of urinary and fecal calcium excretion becomes greater than calcium intake) and thus increase bone loss (11). However, most observational studies have reported either no association or positive associations between protein intake and bone mineral density in children, adults, and elderly subjects (reviewed in 12). The overall calcium balance appears to be unchanged by high dietary protein intake in healthy individuals (13), and current evidence suggests that increased protein intakes in those with adequate supplies of protein, calcium, and vitamin D do not adversely affect BMD or fracture risk (14).

Phosphorus

Phosphorus, which is typically found in protein-rich food, tends to increase the excretion of calcium in the urine. Diets with low calcium-to-phosphorus ratios (Ca:P ≤0.5) have been found to increase parathyroid hormone (PTH) secretion and urinary calcium excretion (15, 16). Also, the intestinal absorption and fecal excretion of calcium and phosphorus are influenced by calcium-to-phosphorus ratios of ingested food. Indeed, in the intestinal lumen, calcium salts can bind to phosphorus to form complexes that are excreted in the feces. This forms the basis for using calcium salts as phosphorus binders to lower phosphorus absorption in individuals with kidney insufficiency (17). Increasing phosphorus intakes from cola soft drinks (high in phosphoric acid) and food additives (high in phosphates) may have adverse effects on bone health (18). At present, there is no convincing evidence that the dietary phosphorus levels experienced in the US adversely affect bone health. Yet, the substitution of large quantities of phosphorus-containing soft drinks for milk or other sources of dietary calcium may represent a serious risk to bone health in adolescents and adults (see the article on Phosphorus).

Caffeine

Exposure to caffeine concentrations ≤400 mg/day have led to increased urinary calcium content in two randomized controlled trials (19, 20). However, caffeine intakes of 400 mg/day did not significantly change urinary calcium excretion over 24 hours in premenopausal women when compared to a placebo (21). A systematic review of 14 studies recently concluded that daily intake of ≤400 mg of caffeine was unlikely to interfere with calcium homeostasis, impact negatively bone mineral density, or increase the risks of osteoporosis and fracture in individuals with adequate calcium intakes (22).

Deficiency

A low blood calcium level (hypocalcemia) usually implies abnormal parathyroid function since the skeleton provides a large reserve of calcium for maintaining normal blood levels, especially in the case of low dietary calcium intake. Other causes of abnormally low blood calcium concentrations include chronic kidney failure, vitamin D deficiency, and low blood magnesium levels often observed in cases of severe alcoholism. Magnesium deficiency can impair parathyroid hormone (PTH) secretion by the parathyroid glands and lower the responsiveness of osteoclasts to PTH. Thus, magnesium supplementation is required to correct hypocalcemia in people with low serum magnesium concentrations (see the article on Magnesium). Chronically low calcium intakes in growing individuals may prevent the attainment of optimal peak bone mass. Once peak bone mass is achieved, inadequate calcium intake may contribute to accelerated bone loss and ultimately to the development of osteoporosis (see Disease Prevention) (1).

The Recommended Dietary Allowance (RDA)

Updated recommendations for calcium intake based on the optimization of bone health were released by the Food and Nutrition Board (FNB) of the Institute of Medicine in 2011 (9). The Recommended Dietary Allowance (RDA) for calcium is listed in **Table 1** by life stage and gender.

Table 1. Recommended Dietary Allowance (RDA) for Calcium

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	200 (AI)	200 (AI)
Infants	6-12 months	260 (AI)	260 (AI)
Children	1-3 years	700	700
Children	4-8 years	1,000	1,000
Children	9-13 years	1,300	1,300
Adolescents	14-18 years	1,300	1,300
Adults	19-50 years	1,000	1,000
Adults	51-70 years	1,000	1,200
Adults	>70 years	1,200	1,200
Pregnancy	14-18 years	-	1,300
Pregnancy	19-50 years	-	1,000
Breast-feeding	14-18 years	-	1,300
Breast-feeding	19-50 years	-	1,000

Disease Prevention

Osteoporosis

Osteoporosis is a skeletal disorder in which bone mass and strength are compromised, resulting in an increased risk of fracture. Sustaining a hip fracture is one of the most serious consequences of osteoporosis. Nearly one-third of those who sustain osteoporotic hip fractures enter nursing homes within a year following the fracture, and one person in four dies within one year of experiencing an osteoporotic hip fracture (23). Despite being a common diagnosis in postmenopausal women, osteoporosis also affects 4%-6% of men over the age of 50 years (24).

Osteoporosis is a multifactorial disorder, and nutrition is only one factor contributing to its development and progression (25). Other factors that increase the risk of developing osteoporosis include, but are not limited to, increased age, female gender, estrogen deficiency, smoking, high alcohol intake (three or more drinks/day), metabolic disease (e.g., hyperthyroidism), and the use of certain medications (e.g., corticosteroids and anticonvulsants) (26). A predisposition to osteoporotic fracture is related to one's peak bone mass and to the rate of bone loss after peak bone mass has been attained. After adult height has been reached, the skeleton continues to accumulate bone until the third decade of life. Genetic factors exert a strong influence on peak bone mass, but lifestyle factors can also play a significant role. Strategies for reducing the risk of osteoporotic fracture include the attainment of maximal peak bone mass and the reduction of bone loss later in life. A number of lifestyle factors, including diet (especially calcium and protein intake) and physical activity, are amenable to interventions aimed at maximizing peak bone mass and limiting osteoporotic fracture risk (27).

Physical exercise is a lifestyle factor that has been associated with numerous health benefits and is likely to contribute to the prevention of osteoporosis and osteoporotic fracture. There is evidence to suggest that physical activity early in life contributes to the attainment of higher peak bone mass (27). Moreover, lifelong participation in physical activities in the presence of adequate calcium and vitamin D supply (from dietary sources and/or sunlight exposure) may have a modest effect on slowing the rate of bone loss later in life (28). Current National Osteoporosis Foundation guidelines include recommendations of regular muscle-strengthening and weight-bearing exercise to all postmenopausal women and men ages 50 and older (29). Although benefits in reducing bone loss might be limited, muscle-strengthening exercise, including weight training and other resistive exercises (e.g., yoga and Pilates) and weight-bearing exercise (e.g., walking, jogging, and stair climbing), may improve strength, posture, balance, and coordination, thus contributing to reduced risk of falls (29). One compilation of published calcium trials indicated that the beneficial skeletal effect of increased physical activity was achievable only at calcium intakes above 1,000 mg/day in women in late menopause (reviewed in 28).

The progressive loss of bone mineral density (BMD) leading to osteopenia (pre-osteoporosis) and osteoporosis is usually assessed by dual-energy x-ray absorptiometry (DEXA) at the hip and lumbar spine (30). Several randomized, placebo-controlled clinical trials have evaluated the effect of supplemental calcium in the preservation of BMD and the prevention of fracture risk in men and women aged 50 years and older. A meta-analysis of 15 randomized controlled trials, including 1,533 men and women >50 years of age, found that increasing calcium intake from dietary sources (i.e., milk, milk powder, dairy products, or hydroxyapatite preparations) increased BMD by 0.6%-1% at the hip (+0.6%) and total body (+1.0%) after one year and by 0.7%-1.8% at the lumbar spine (+0.7%), femoral neck (+1.8%), total hip (+1.5%), and total body (+0.9%) sites after two years (31). A meta-analysis of 51 randomized controlled trials in 12,257 adults (>50 years) found that BMD at all bone sites (lumbar spine, femoral neck, total hip, forearm) increased by 0.7%-1.4% after one year and 0.8%-1.5% after two years of supplemental calcium, alone or in combination with vitamin D (31). Such modest increases may help limit the average rate of BMD loss after menopause but are unlikely to translate into meaningful fracture risk reductions. A meta-analysis of 20 randomized controlled trials that reported on total fracture risk found an 11% risk reduction associated with supplemental calcium with or without vitamin D (32). However, there was no effect when the analysis was restricted to the largest trials with the lowest risk of bias. Additionally, no reductions were found in risks of hip, vertebral and forearm fractures with calcium supplementation (32). Because estrogen withdrawal significantly impairs intestinal absorption and renal reabsorption of calcium, the level of calcium requirement might depend on whether postmenopausal women receive hormone replacement therapy (28).

The US Preventive Services Task Force conducted a meta-analysis of 11 randomized placebo-controlled trials that included 52,915 older people (of whom 69% were postmenopausal women) and reported that the supplementation of vitamin D (300-1,000 IU/day) and calcium (500-1,200 mg/day) for up to seven years resulted in a 12% reduction in the risk of any new fracture (33). There was no significant effect of vitamin D without calcium (33). A recently updated meta-analysis of randomized, placebo-controlled trials commissioned by the National Osteoporosis Foundation found a 15% reduction in risk of total fracture (8 studies) and a 30% reduction in risk of hip fractures (six studies) with calcium and vitamin D supplementation in older people (34). The National Osteoporosis Foundation advises that adequate intake of calcium (1,000-1,200 mg/day) and vitamin D (800-1,000 IU/day) be included in the diet of all middle-aged men and women (35).

The role and efficacy of vitamin D supplementation in strengthening bone and preventing fracture in older people remain controversial topics. The active form of vitamin D, 1,25-dihydroxyvitamin D, stimulates calcium absorption by promoting the synthesis of calcium-binding proteins in the intestine. While no amount of vitamin D can compensate inadequate total calcium intake, vitamin D insufficiency (defined as circulating concentrations of 25-hydroxyvitamin D below 20 ng/mL [50 nmol/L]) can lead to secondary hyperparathyroidism and an increased risk of osteoporosis (9, 36). Conversely, in postmenopausal women (ages 57-90 years) with adequate total calcium intakes (1,400 IU/day), serum 25-hydroxyvitamin D concentrations ranging from 20 ng/mL to 66 ng/mL had little effect on calcium absorption (only 6% increase over the range) (37). In a randomized, placebo-controlled trial, the supplementation of 1,000 IU/day of vitamin D to postmenopausal women (mean age, 77.2 years) for one year was found to significantly increase circulating 25-hydroxyvitamin D concentrations by 34% from baseline but failed to enhance calcium absorption in the presence of high total calcium intakes (dietary plus supplemental calcium corresponding to an average 2,100 mg/day) (38). This study also reported no significant difference in measures of BMD at the hip and total body between placebo- and vitamin D-treated women. In addition, the pooled analysis of seven randomized controlled trials, including 65,517 older individuals living in the community or in an institution, found that vitamin D (400-800 IU/day) could reduce the risk of any fracture only when combined with calcium (1,000 mg/day) (39). Interestingly, the results of a series of trials included in three recent meta-analyses (33, 40, 41) have suggested that supplemental vitamin D and calcium may have greater benefits in the prevention of fracture in institutionalized, older people who are also at increased risk of vitamin D deficiency and fractures compared to community dwellers (42, 43).

For more information about bone health and osteoporosis, see the article, Micronutrients and Bone Health, and visit the National Osteoporosis Foundation website.

Kidney stones

Approximately 6% of women and 15% of men in industrialized countries will have a kidney stone during their lifetime. Most kidney stones are composed of calcium oxalate or calcium phosphate. Subjects with an abnormally high level of calcium in the urine (hypercalciuria) are at higher risk of developing kidney stones (a process called nephrolithiasis) (44). High urinary oxalate level is another risk factor for calcium oxalate stone formation. Most subjects with a history of kidney stones and/or idiopathic hypercalciuria have increased intestinal calcium absorption (45). Although it was initially recommended to limit dietary calcium intake in these patients, a number of prospective cohort studies have reported associations between lower total dietary calcium intake and increased risk of incident kidney stones (46-48). The prospective analyses of three large cohorts, including a total of 30,762 men and 195,865 women followed for a combined 56 years, have indicated that the risk of kidney stones was significantly lower in individuals in the highest versus lowest quintile of dietary calcium intake from dairy or nondairy sources (49). Additionally, a five-year randomized intervention study that enrolled 120 men with idiopathic hypercalciuria (mean age, 45 years) reported that those assigned to a low-calcium diet (approximately 400 mg/day) had a 51% higher risk of kidney stone recurrence compared to those on a normal-to-high calcium (1,200 mg/day), low animal-protein, low-salt diet (50).

Mechanisms by which increased dietary calcium might reduce the risk of incident kidney stones are not fully understood. An inverse relationship was reported between total calcium intake and intestinal calcium absorption in the recent cross-sectional analysis of a cohort of 5,452 postmenopausal women (45). Moreover, women with higher supplemental calcium intake and lower calcium absorption were less likely to report a history of kidney stones (45). Adequate intake of calcium with food may reduce the absorption of dietary oxalate and lower urinary oxalate through formation of the insoluble calcium oxalate salt (51, 52). A recent small intervention study in 10 non-stone-forming young adults observed that the ingestion of large amounts of oxalate did not increase the risk of calcium oxalate stone occurrence in the presence of recommended level of dietary calcium (53).

However, a randomized, double-blind, placebo-controlled trial in 36,282 postmenopausal women reported that a combination of supplemental calcium (1,000 mg/day) and vitamin D (400 IU/day) was associated with a significantly increased incidence of self-reported kidney stones during a seven-year treatment period. More controlled trials may be necessary to determine whether supplemental calcium affects kidney stone risk (54). However, a systematic review of observational studies and randomized controlled trials that primarily reported on bone-related outcomes failed to find an effect of calcium supplementation on stone incidence (55). A potential kidney stone risk associated with calcium supplementation may likely depend on whether supplemental calcium is co-ingested with oxalate-containing foods or consumed separately. Further research is needed to verify whether osteoporosis treatment drugs (e.g., biphosphonates) rather than calcium supplements might influence the risk of stone occurrence (56).

Current data suggest that diets providing adequate dietary calcium and low levels of animal protein, oxalate, and sodium may benefit the prevention of stone recurrence in subjects with idiopathic hypercalciuria (57-59).

Hypertensive disorders of pregnancy

Pregnancy-induced hypertensive disorders, including gestational hypertension, preeclampsia, and eclampsia, complicate approximately 10% of pregnancies and are a major health risk for pregnant women and their offspring (60). Gestational hypertension is defined as an abnormally high blood pressure that usually develops after the 20th week of pregnancy. Preeclampsia is characterized by poor placental perfusion and a systemic inflammation that may involve several organ systems, including the cardiovascular system, kidneys, liver, and hematological system (61). In addition to gestational hypertension, preeclampsia is associated with the development of severe swelling (edema) and the presence of protein in the urine (proteinuria). Eclampsia is the occurrence of seizures in association with the syndrome of preeclampsia and is a significant cause of maternal and perinatal mortality.

Although cases of preeclampsia are at high risk of developing eclampsia, one-quarter of women with eclampsia do not initially exhibit preeclamptic symptoms. Risk factors for preeclampsia include genetic predisposition, advanced maternal age, first pregnancies, multiple pregnancies (e.g., twins or triplets), obesity, diabetes, and some autoimmune diseases (61). While the pathogenesis of preeclampsia is not entirely understood, nutrition and especially calcium metabolism appear to play a role. Data from epidemiological studies have suggested an inverse relationship between calcium intake during pregnancy and the incidence of preeclampsia (reviewed in 62). Impairment of calcium metabolism when circulating vitamin D concentration is low and/or when dietary calcium intake is inadequate may contribute to the risk of hypertension during pregnancy.

Secondary hyperparathyroidism (high PTH level) due to vitamin D deficiency in young pregnant women has been associated with high maternal blood pressure and increased risk of preeclampsia (63). The risk for elevated PTH concentration was also found to be increased in vitamin D-sufficient women with low-calcium intakes (<480 mg/day) during pregnancy when compared with adequate-to-high calcium intakes (≥1,000 mg/day) (64). In addition, vitamin D deficiency may trigger hypertension through the inappropriate activation of the renin-angiotensin system (see the article on Vitamin D).

Potential beneficial effects of calcium in the prevention of preeclampsia have been investigated in several randomized, placebo-controlled studies. The most recent meta-analysis of 13 trials in 15,730 pregnant women found that calcium supplementation with at least 1,000 mg/day (mostly 1,500-2,000 mg/day) from about 20 weeks of pregnancy (34 weeks of pregnancy at the latest) was associated with significant reductions in the risk of high blood pressure, preeclampsia, and preterm birth (62). Greater risk reductions were reported among pregnant women at high risk of preeclampsia (5 trials; 587 women) or with low dietary calcium intake (8 trials; 10,678 women). Another meta-analysis of nine randomized controlled trials in high-risk women indicated that lower doses of calcium supplementation (≤800 mg/day), alone or with a co-treatment (i.e., vitamin D, linoleic acid, or antioxidants), could also lower the risk of preeclampsia by 62% (65). Yet, based on the systematic review of high-quality randomized controlled trials, which used mostly high-dose calcium supplements, the World Health Organization (WHO) recently recommended that all pregnant women in areas of low-calcium intake (i.e., low-income countries with intakes around 300-600 mg/day) be given 1.5 to 2 g (1,500 to 2,000 mg)/day of elemental calcium from the 20th week of pregnancy (66).

Because excessive calcium supplementation may be harmful (see Safety), further research is required to verify whether calcium supplementation above the current IOM recommendation (1,000 mg/day for pregnant women, ages 19-50 years) would provide greater benefits to women at high risk of preeclampsia. Finally, the lack of effect of supplemental calcium on proteinuria (reported in two trials only) suggested that calcium supplementation from mid-pregnancy might be too late to oppose the genesis of preeclampsia (67, 68). A randomized, double-blind, placebo-controlled study — the WHO Calcium and Pre-eclampsia (CAP) trial — is ongoing to evaluate the effect of calcium supplementation with 500 mg/day, starting before pregnancy and until the 20th week of pregnancy, on the risk of preeclampsia in high-risk women (69, 70).

Colorectal cancer

Colorectal cancer (CRC) is the most common gastrointestinal cancer and the second leading cause of cancer death in the US (71). CRC is caused by a combination of genetic and environmental factors, but the degree to which these two types of factors influence CRC risk in individuals varies widely. In individuals with familial adenomatous polyposis (FAP) or hereditary nonpolyposis colorectal cancer (HNPCC), the cause of CRC is almost entirely genetic, while modifiable lifestyle factors, including dietary habits, tobacco use, and physical activities, greatly influence the risk of sporadic (non-hereditary) CRC.

Prospective cohort studies have consistently reported an inverse association between dairy food consumption and CRC risk. Experimental studies in cell culture and animal models have suggested plausible mechanisms underlying a role for calcium, a major nutrient in dairy products, in preventing CRC (72). In the multicenter European Prospective Investigation into Cancer and Nutrition (EPIC) prospective study of 477,122 individuals, followed for an average of 11 years, 4,513 CRC cases were documented (73). Intakes of milk, cheese, and yogurt, were inversely associated with CRC risk. The highest versus lowest quintile of total dairy intake (≥490 g/day vs. <134 g/day) was associated with a 23% lower risk of CRC. Similarly, CRC risk was 25% lower in those in the top versus bottom quintile of calcium intake from dairy food (≥839 mg/day vs. <308 mg/day). The 16-year follow-up of 41,403 women (ages 26-46 years at inclusion) from the prospective Nurses' Health Study II (NHS II) documented 2,273 diagnoses of colorectal adenomas (precancerous polyps). The analysis of the prospective cohort found that women with total calcium intake of 1,001-1,250 mg/day had a 76% lower risk of developing advanced adenomas (i.e., adenomas more likely to become malignant) compared to those with intakes equal to and below 500 mg/day (74). In addition, a dose-response analysis using data from eight prospective studies (11,005 CRC cases) estimated that an increase of 300 mg/day in total calcium intake was associated with a 5% reduction in CRC risk (75). Total daily intake of calcium ranged from 333 to 2,229 mg in the examined studies. In addition, the dose-response analysis of six prospective studies (8,839 CRC cases among 920,837 participants) showed 11% lower odds of high-risk adenomas for each 300 mg/day increment in total calcium (75).

However, the meta-analysis of seven randomized, double-blind, placebo-controlled studies found no evidence of an effect of calcium supplementation (≥500 mg/day) for a median period of 45 months on total cancer risk and CRC risk (76). In addition, the re-analysis of the Women's Health Initiative placebo-controlled trial failed to show a reduction in CRC risk in postmenopausal women supplemented with both vitamin D (400 IU/day) and calcium (1,000 mg/day) for seven years (77). Finally, the results of the meta-analysis of four randomized, placebo-controlled trials have suggested that calcium supplementation (1,200-2,000 mg/day) may reduce the risk of adenoma recurrence by 13% over three to five years in subjects with a history of adenomas (78). At present, it is not clear whether calcium supplementation is beneficial in CRC prevention. Larger trials designed to assess primarily the effect of long-term calcium supplementation on the incidence of adenomas and/or CRC are needed before conclusions can be drawn.

Lead toxicity

Children who are chronically exposed to lead, even in small amounts, are more likely to develop learning disabilities, behavioral problems, and to have low IQs. Deficits in growth and neurological development may occur in the infants of women exposed to lead during pregnancy and lactation. In adults, lead toxicity may result in kidney damage and high blood pressure. Although the use of lead in paint products, gasoline, and food cans has been discontinued in the US, lead toxicity continues to be a significant health problem, especially in children living in urban areas (79).

In 2012, the US Centers for Disease Control and Prevention set the reference value for blood lead concentration at 5 micrograms per deciliter (mg/dL) to identify children at risk (80). Yet, there is no known blood lead concentration below which children are 100% safe. An early study of over 300 children in an urban neighborhood found that 49% of children ages 1 to 8 years had blood lead levels above the threshold of 10 mg/dL, indicating excessive lead exposure. In this study, only 59% of children ages 1 to 3 years and 41% of children ages 4 to 8 years met the recommended levels for calcium intakes (81).

Adequate calcium intake could be protective against lead toxicity in at least two ways. Increased dietary intake of calcium is known to decrease the gastrointestinal absorption of lead. Once lead enters the body it tends to accumulate in the skeleton, where it may remain for more than 20 years. Adequate calcium intake also prevents lead mobilization from the skeleton during bone demineralization. A study of circulating concentrations of lead during pregnancy found that women with inadequate calcium intake during the second half of pregnancy were more likely to have elevated blood lead levels, probably because of increased bone demineralization, leading to the release of accumulated lead into the blood (82). Lead in the blood of a pregnant woman is readily transported across the placenta resulting in fetal lead exposure at a time when the developing nervous system is highly vulnerable. In a randomized, double-blind, placebo-controlled study in 670 pregnant women (≤14 weeks' gestation) with average dietary calcium intakes of 900 mg/day, daily supplementation of 1,200 mg of calcium throughout the pregnancy period resulted in 8%-14% reductions in maternal blood lead concentrations (83). Similar reductions in maternal lead concentrations in the blood and breast milk of lactating mothers supplemented with calcium were reported in earlier trials (84, 85). In postmenopausal women, factors known to decrease bone demineralization, including estrogen replacement therapy and physical activity, have been inversely associated with blood lead levels (86).

Disease Treatment

Overweight and obesity

High dietary calcium intake, usually associated with dairy product consumption, has been inversely related to body weight and central obesity in a number of cross-sectional studies (reviewed in 87). Cross-sectional baseline data analyses of a number of prospective cohort studies that were not designed and powered to examine the effect of calcium intake or dairy consumption on obesity or body fat have given inconsistent results (87). Yet, a meta-analysis of 18 cross-sectional and prospective studies predicted a reduction in body mass index (a relative measure of body weight; BMI) of 1.1 kg/m^2 with an increase in calcium intake from 400 mg/day to 1,200 mg/day (87). In a placebo-controlled intervention study, 32 obese subjects were randomized to energy restriction regimens (500 kCal/day deficit) for 24 weeks with (1) a standard diet providing 400 to 500 mg/day of dietary calcium and a placebo ("low calcium" diet), (2) a standard diet and 800 mg/day of supplemental calcium ("high calcium" diet), or (3) a high-dairy diet providing 1,200 mg/day of dietary calcium and a placebo (88). Energy-restricted diets resulted in significant body weight and fat loss in all three groups. Yet, body weight and fat loss were significantly more reduced with the high-calcium diet compared to the standard diet, and further reductions were measured with the high-dairy diet compared to both high-calcium and low-calcium diets. These results suggested that while calcium intake may play a role in body weight regulation, additional benefits might be attributable to other bioactive components of dairy products, such as proteins, fatty acids, and branched chain amino acids.

Yet, several mechanisms have been proposed to explain the potential impact of calcium on body weight (reviewed in 87). The most-cited mechanism is based on studies in the agouti mouse model showing that low-calcium intakes, through increasing circulating parathyroid hormone (PTH) and vitamin D, could stimulate the accumulation of fat (lipogenesis) in adipocytes (fat cells) (89). Conversely, higher intakes of calcium may reduce fat storage, stimulate the breakdown of lipids (lipolysis), and drive fat oxidation. A recent meta-analysis of randomized controlled trials estimated that high (1,300 mg/day) versus low (488 mg/day) calcium intake for a minimum of seven days increased fat oxidation by 11% (90). However, a double-blind, placebo-controlled, randomized, cross-over trial in 10 low-calcium consuming overweight or obese individuals reported that the supplementation with 800 mg/day of calcium for 5 weeks failed to modify the expression of key factors involved in fat metabolism (91). Moreover, while the model suggests a role for vitamin D in lipogenesis (fat storage), human studies have shown that vitamin D deficiency — rather than sufficiency — is often associated with obesity, and supplemental vitamin D might be effective in lowering body weight when caloric restriction is imposed (92, 93). Another mechanism suggests that high-calcium diets may limit dietary fat absorption in the intestine and increase fecal fat excretion. Indeed, in the gastrointestinal tract, calcium may trap dietary fat into insoluble calcium soaps of fatty acids that are then excreted (94). In addition, despite very limited evidence, it has also been proposed that calcium might be involved in regulating appetite and energy intake (95).

To date, there is no consensus regarding the effect of calcium on body weight changes. A meta-analysis of 29 randomized controlled trials in 2,441 participants (median age, 41.4 years) found that calcium supplementation was only associated with body weight and fat loss in short-term studies (<1 year) that used energy-restricted diets (96). Another meta-analysis of 41 randomized controlled trials (4,802 participants) found little-to-no effect of increased calcium intake from supplements or dairy foods for >12 weeks on body weight and body composition (97). Finally, a meta-analysis of 33 randomized controlled trials (4,733 participants) found no overall effect of calcium supplementation (from food or supplements) for >12 weeks on body weight changes. Yet, further subgroup analyses showed weight reductions in children and adolescents (mean, -0.26 kg), in adults (mean, -0.91 kg), and in those with normal BMI (mean, -0.53 kg). Supplemental calcium did not lead to weight loss in postmenopausal women or in overweight/obese individuals (98). At present, additional research is warranted to examine the effect of calcium intake on fat metabolism, as well as its potential benefits in the management of body weight with or without caloric restriction (99).

Premenstrual Syndrome (PMS)

PMS refers to a cluster of symptoms, including but not limited to fatigue, irritability, moodiness/depression, fluid retention, and breast tenderness, that begins sometime after ovulation (mid-cycle) and subsides with the onset of menstruation (the monthly period) (100). A severe form of PMS called premenstrual dysphoric disorder (PMDD) has been described in 3%-8% of women of childbearing age. PMDD interferes with normal functioning, affecting daily activities and relationships (101).

Low dietary calcium intakes have been linked to PMS in early reports, and supplemental calcium has been shown to decrease symptom severity (102). A nested case-control study within the Nurses' Health Study II (NHS II) found that women in the highest quintile of dietary (but not supplemental) calcium intake (median of 1,283 mg/day) had a 30% lower risk of developing PMS compared to those in the lowest quintile (median of 529 mg/day). Similarly, women in the highest versus lowest quintile of skim or low-fat milk intake (≥4 servings/day vs. ≤1 serving/week) had a 46% lower risk of PMS (103). In a randomized, double-blind, placebo-controlled clinical trial of 466 women with moderate-to-severe premenstrual symptoms, supplemental calcium (1,200 mg/day) for three menstrual cycles was associated with a 48% reduction in total symptom scores, compared to a 30% reduction observed in the placebo group (104). Similar positive effects were reported in earlier double-blind, placebo-controlled, cross-over trials that administered 1,000 mg of calcium daily (105, 106). Recent small randomized controlled trials also reported that supplemental calcium (400-500 mg/day) for three weeks to three months reduced severity and/or frequency of symptoms in women with mild-to-moderate PMS (107-110). Currently available data indicate that daily calcium intakes from food and/or supplements may have therapeutic benefits in women diagnosed with PMS or PMDD (111, 112).

Hypertension

The relationship between calcium intake and blood pressure has been investigated extensively over the past decades. A meta-analysis of 23 large observational studies conducted in different populations worldwide found a reduction in systolic blood pressure of 0.34 millimeters of mercury (mm Hg) per 100 mg of calcium consumed daily and a reduction in diastolic blood pressure of 0.15 mm Hg per 100 mg calcium (113). In the DASH (Dietary Approaches to Stop Hypertension) study, 549 people were randomized to one of three diets for eight weeks: (1) a control diet that was low in fruit, vegetables, and dairy products; (2) a diet rich in fruit (~5 servings/day) and vegetables (~3 servings/day); and (3) a combination diet rich in fruit and vegetables, as well as low-fat dairy products (~3 servings/day) (114). The combination diet represented an increase of about 800 mg of calcium/day over the control and fruit/vegetable-rich diets for a total of about 1,200 mg of calcium/day. Overall, the reduction in systolic blood pressure was greater with the combination diet than with the fruit/vegetable diet or the control diet. Among participants diagnosed with hypertension, the combination diet reduced systolic blood pressure by 11.4 mm Hg and diastolic pressure by 5.5 mm Hg more than the control diet, while the reduction for the fruit/vegetable diet was 7.2 mm Hg for systolic and 2.8 mm Hg for diastolic blood pressure compared to the control diet (115). This research suggested that calcium intake at the recommended level (1,000-1,200 mg/day) may be helpful in preventing and treating moderate hypertension (116).

Yet, two large systematic reviews and meta-analyses of randomized controlled trials have examined the effect of calcium supplementation on blood pressure compared to placebo in either normotensive or hypertensive individuals (117, 118). Neither of the analyses reported any significant effect of supplemental calcium on blood pressure in normotensive subjects. A small but significant reduction in systolic blood pressure, but not in diastolic blood pressure, was reported in participants with hypertension. Of note, calcium supplementation in these randomized controlled trials ranged from 400 to 2,200 mg/day, with 1,000 to 1,500 mg/day being the more common dosages. A more recent meta-analysis of 13 randomized controlled studies in 485 individuals with elevated blood pressure found a significant reduction of 2.5 mm Hg in systolic blood pressure but no change in diastolic blood pressure with calcium supplementation (119). The modest effect of calcium on blood pressure needs to be confirmed in larger, high-quality, well-controlled trials before any recommendation is made regarding the management of hypertension. Finally, a review of the literature on the effect of high-calcium intake (dietary and supplemental) in postmenopausal women found either no reduction or mild and transient reductions in blood pressure (120).

More information about the DASH diet is available from the National Institutes of Health (NIH).

Sources

Food sources

Data analysis of the US National Health and Nutrition Examination Surveys (NHANES) 2009-2010 and 2011-2012 found inadequate calcium intakes (defined as intakes below the Estimated Average Requirement [EAR]) in 37.7% of non-supplemented adults (ages, ≥19 years) and 19.6% of adults taking multivitamin/mineral supplements (121). Dairy foods provide 75% of the calcium in the American diet. However, it is typically during the most critical period for peak bone mass development that adolescents tend to replace milk with soft drinks (122). Dairy products represent rich and absorbable sources of calcium, but certain vegetables and grains also provide calcium.

However, the bioavailability of the calcium must be taken into consideration. The calcium content in calcium-rich plants in the kale family (broccoli, bok choy, cabbage, mustard, and turnip greens) is as bioavailable as that in milk; however, other plant-based foods contain components that inhibit the absorption of calcium. Oxalic acid, also known as oxalate, is the most potent inhibitor of calcium absorption and is found at high concentrations in spinach and rhubarb and somewhat lower concentrations in sweet potatoes and dried beans. Phytic acid (phytate) is a less potent inhibitor of calcium absorption than oxalate. Yeast possess an enzyme (phytase) that breaks down phytate in grains during fermentation, lowering the phytate content of breads and other fermented foods. Only concentrated sources of phytate, such as wheat bran or dried beans, substantially reduce calcium absorption (123).

Additional dietary constituents may affect calcium absorption (see Nutrient interactions). **Table 2** lists a number of calcium-rich foods, along with their calcium content. For more information on the nutrient content of foods, search USDA's FoodData Central.

Table 2. Some Food Sources of Calcium

Food	Serving	Calcium (mg)
Tofu prepared with calcium sulfate (raw)	½ cup	434
Yogurt, plain, low-fat	8 ounces	415
Sardines, canned	3.75 ounces (1 can)	351
Cheddar cheese	1.5 ounces	303
Milk	8 ounces	300
White beans (cooked)	½ cup	81
Chinese cabbage (Bok choy/Pak choi, cooked)	½ cup	79
Figs (dried)	¼ cup	61
Orange	1 medium	60
Kale (cooked)	½ cup	47
Pinto beans (cooked)	½ cup	39
Broccoli (cooked)	½ cup	31
Red beans (cooked)	½ cup	25

Supplements

Most experts recommend obtaining as much calcium as possible from food because calcium in food is accompanied by other important nutrients that assist the body in utilizing calcium. However, calcium supplements may be necessary for those who have difficulty consuming enough calcium from food (124). No multivitamin/mineral tablet contains 100% of the recommended daily value (DV) for calcium because it is too bulky, and the resulting pill would be too large to swallow. The "Supplement Facts" label, required on all supplements marketed in the US, lists the calcium content of the supplement as elemental calcium. Calcium preparations used as supplements include calcium carbonate, calcium citrate, calcium citrate malate, calcium lactate, and calcium gluconate. To determine which calcium preparation is in your supplement, you may have to look at the ingredient list. Calcium carbonate is generally the most economical calcium supplement. To maximize absorption, take no more than 500 mg of elemental calcium at one time. Most calcium supplements should be taken with meals, although calcium citrate and calcium citrate malate can be taken anytime. Calcium citrate is the preferred calcium formulation for individuals who lack stomach acids (achlorhydria) or those treated with drugs that limit stomach acid production (H_2 blockers and proton-pump inhibitors) (reviewed in 125).

Lead in calcium supplements

Several decades ago, concern was raised regarding lead concentrations in calcium supplements obtained from natural sources (oyster shell, bone meal, dolomite) (126). In 1993, investigators found measurable quantities of lead in most of the 70 different preparations they tested (127). Since then, manufacturers have reduced the amount of lead in calcium supplements to less than 0.5 micrograms (mg)/1,000 mg of elemental calcium (128). The US Food and Drug Administration (FDA) has developed provisional total tolerable intake levels (PTTI) for lead for specific age and sex groups (129). Because lead is so widespread and long lasting, no one can guarantee entirely lead-free food or supplements. A study found measurable lead in 8 out of 21 supplements, in amounts averaging 1 to 2 mg/1,000 mg of elemental calcium, which is below the tolerable limit of 7.5 mg/1,000 mg of elemental calcium (130). A more recent survey of 324 multivitamin/mineral supplements labeled for use in children or women found that most supplements would result in lead exposure ranging from 1%-4% of the PTTI (131).

Calcium inhibits intestinal absorption of lead, and adequate calcium intake is protective against lead toxicity, so trace amounts of lead in calcium supplementation may pose less of a risk of excessive lead exposure than inadequate calcium consumption. While most calcium sources today are relatively safe, look for supplements approved or certified by independent testing (e.g., US Pharmacopeia, ConsumerLab.com) (125), follow label instructions, and avoid large doses of supplemental calcium (≥1,500 mg/day).

Safety

Toxicity

Malignancy and primary hyperparathyroidism are the most common causes of elevated calcium concentrations in the blood (hypercalcemia) (132). Hypercalcemia has not been associated with the over consumption of calcium occurring naturally in food. Hypercalcemia has been initially reported with the consumption of large quantities of calcium supplements in combination with antacids, particularly in the days when peptic ulcers were treated with large quantities of milk, calcium carbonate (antacid), and sodium bicarbonate (absorbable alkali). This condition is termed calcium-alkali syndrome (formerly known as milk-alkali syndrome) and has been associated with calcium supplement levels from 1.5 to 16.5 g/day for 2 days to 30 years. Since the treatment for peptic ulcers has evolved and because of the widespread use of over-the-counter calcium supplements, the demographic of this syndrome has changed in that those at greater risk are now postmenopausal women, pregnant women, transplant recipients, patients with bulimia, and patients on dialysis, rather than men with peptic ulcers (reviewed in 133). Supplementation with calcium (0.6 g/day-2 g/day for two to five years) has been associated with a higher risk of adverse gastrointestinal events like constipation, cramping, bloating, pain, diarrhea (134). Mild hypercalcemia may be without symptoms or may result in loss of appetite, nausea, vomiting, constipation, abdominal pain, fatigue, frequent urination (polyuria), and hypertension (132). More severe hypercalcemia may result in confusion, delirium, coma, and if not treated, death (1).

In 2011, the Food and Nutrition Board of the Institute of Medicine updated the tolerable upper intake level (UL) for calcium (9). The UL is listed in **Table 3** by age group.

Table 3. Tolerable Upper Intake Level (UL) for Calcium

Age Group	UL (mg/day)
Infants 0-6 months	1,000
Infants 6-12 months	1,500
Children 1-8 years	2,500
Children 9-13 years	3,000
Adolescents 14-18 years	3,000
Adults 19-50 years	2,500
Adults 51 years and older	2,000

Although the risk of forming kidney stones is increased in individuals with abnormally elevated urinary calcium (hypercalciuria), this condition is not usually related to calcium intake, but rather to increased absorption of calcium in the intestine or increased excretion by the kidneys (9). Overall, increased dietary calcium intake has been associated with a decreased risk of kidney stones (see Kidney stones). Concerns have also been raised regarding the risks of prostate cancer and vascular disease with high intakes of calcium.

Do high calcium intakes increase the risk for prostate cancer?

Prostate cancer is the second most common cancer in men worldwide (135). Several observational studies have raised concern that high-dairy intakes are associated with increased risk of prostate cancer (136-138).

The analysis of a prospective cohort study (2,268 men followed for nearly 25 years) conducted in Iceland, a country with a high incidence of prostate cancer, found a positive association between the consumption of milk (at least once daily) during adolescence and developing prostate cancer later in life (139). Another large prospective cohort study in the US followed 21,660 male physicians for 28 years and found that men with daily skim or low-fat milk intake of at least 237 mL (8 oz) had a higher risk of developing prostate cancer compared to occasional consumers (140). The risk of low-grade, early-stage prostate cancer was associated with higher intake of skim milk, and the risk of developing fatal prostate cancer was linked to the regular consumption of whole milk (140). In a cohort of 3,918 male health professionals diagnosed with prostate cancer, 229 men died of prostate cancer and 69 developed metastasized prostate cancer during a median follow-up of 7.6 years (141). The risk of prostate cancer death was found to be increased in men with high (>4 servings/week) versus low (≤3 servings/month) intakes of whole milk. Yet, no increase in risk of prostate cancer-related mortality was associated with consumption of skim and low-fat milk, total milk, low-fat dairy products, full-fat dairy products, or total dairy products (141). A recent meta-analysis of 32 prospective cohort studies found high versus low intakes of total dairy product (15 studies), total milk (15 studies), whole milk (6 studies), low-fat milk (5 studies), cheese (11 studies), and dairy calcium (7 studies) to be associated with modest, yet significant, increases in the risk of developing prostate cancer (142). However, there was no increase in prostate cancer risk with nondairy calcium (4 studies) and calcium from supplements (8 studies). Moreover, high dairy intakes were not linked to fatal prostate cancer (142).

There is some evidence to suggest that milk consumption may result in higher circulating concentrations of insulin-like growth factor-I (IGF-I), a protein known to regulate cell proliferation (143). Circulating IGF-I concentrations have been positively correlated to the risk of developing prostate cancer in a recent meta-analysis of observational studies (144). Milk-borne IGF-I, as well as dairy proteins and calcium, may contribute to increasing circulating IGF-I in milk consumers (143). In the large EPIC study, which examined the consumption of dairy products in relation to cancer in 142,520 men, the risk of prostate cancer was found to be significantly higher in those in the top versusbottom quintile of both protein and calcium intakes from dairy foods (145). Another mechanism underlying the potential relationship between calcium intake and prostate cancer proposed that high levels of dietary calcium may lower circulating concentrations of 1,25-dihydroxyvitamin D, the active form of vitamin D, thereby suppressing vitamin D-mediated cell differentiation (146). However, studies to date have provided little evidence to suggest that vitamin D status can modify the association between dairy calcium and risk of prostate cancer development and progression (147-149).

In a multicenter, double-blind, placebo-controlled trial, 672 healthy men (mean age of 61.8 years) were randomized to daily calcium supplementation (1,200 mg) for four years. While no increase in the risk for prostate cancer has been reported during a 10.3-year follow-up, calcium supplementation resulted in a significant risk reduction in the period spanning from two years after treatment started to two years after treatment ended (150). In a review of the literature published in 2009, the US Agency for Healthcare Research and Quality indicated that not all epidemiological studies found an association between calcium intake and prostate cancer (151). The review reported that 6 out of 11 observational studies failed to find statistically significant positive associations between prostate cancer and calcium intake. Yet, in five studies, daily intakes of 921 to 2,000 mg of calcium were found to be associated with an increased risk of developing prostate cancer when compared to intakes ranging from 455 to 1,000 mg/day (151). Inconsistencies among studies suggest complex interactions between the risk factors for prostate cancer, as well as reflect the difficulties of assessing the effect of calcium intake in free-living individuals. For example, the fact that individuals with higher dairy and/or calcium intakes were found to be more likely to be engaged in healthy lifestyles or more likely to seek medical attention can mitigate the statistical significance of an association with prostate cancer risk (152). Until the relationship between calcium and prostate cancer is clarified, it is reasonable for men to consume a total of 1,000 to 1,200 mg/day of calcium (diet and supplements combined), which is recommended by the Food and Nutrition Board of the Institute of Medicine (see RDA) (9).

Do calcium supplements increase the risk for cardiovascular disease?

Several observational studies and randomized controlled trials have raised concerns regarding the potential adverse effects of calcium supplements on cardiovascular risk. The analysis of data from the Kuopio Osteoporosis Risk Factor and Prevention (OSTPRE) prospective study found that users of calcium supplements amongst 10,555 Finnish women (ages 52-62 years) had a 14% greater risk of developing coronary artery disease compared to non-supplement users during a mean follow-up of 6.75 years (153). The prospective study of 23,980 participants (35-64 years old) of the Heidelberg cohort of the European Prospective Investigation into Cancer and Nutrition cohort (EPIC-Heidelberg) observed that supplemental calcium intake was positively associated with the risk of myocardial infarction (heart attack) but not with the risk of stroke or cardiovascular disease (CVD)-related mortality after a mean follow-up of 11 years (154). Yet, the use of calcium supplements (≥400 mg/day vs. 0 mg/day) was associated with an increased risk of CVD-related mortality in 219,059 men, but not in 169,170 women, included in the National Institute of Health (NIH)-AARP Diet and Health study and followed for a mean period of 12 years. CVD mortality in men was also found to be significantly higher with total (dietary plus supplemental) calcium intakes of 1,500 mg/day and above (155).

In addition, the secondary analyses of two randomized placebo-controlled trials initially designed to assess the effect of calcium on bone health outcomes also suggested an increased risk of CVD in participants daily supplemented with 1,000 mg of calcium for five to seven years (156, 157). In the Auckland Calcium Study of 1,471 healthy postmenopausal women (ages ≥55 years), calcium supplementation resulted in increased risks of myocardial infarction and of a composite cardiovascular endpoint, including myocardial infarction, stroke, or sudden death (156). The analysis of data from 36,282 healthy postmenopausal women randomized to receive a combination of calcium (1,000 mg/day) and vitamin D (400 IU/day) or a placebo in the Women's Health Initiative/Calcium-Vitamin D supplementation study (WHI/CaD study) initially reported no adverse effect on any cardiovascular endpoints with calcium (and vitamin D) compared to placebo (158). A re-analysis was performed with data from 16,718 women who did not take personal calcium supplements (outside protocol) during the five-year study (157). Although criticized on the approach taken (134, 159), the investigators estimated that women supplemented with calcium and vitamin D had a 16% increased risk of clinical myocardial infarction or stroke and a 21% increased risk of myocardial infarction compared to those who received a placebo (157). However, in another randomized, double-blind, placebo-controlled trial — the Calcium Intake Fracture Outcome (CAIFOS) study — in elderly women (median age, 75.1 years), the supplementation of 1,200 mg/day of calcium for five years was not found to increase the risk of vascular disease or related mortality (160). The WHI/CaD data re-analysis also failed to show an increased risk of mortality due to myocardial infarction or coronary artery disease with calcium therapy (156). Also, after an additional follow-up of 4.5 years at the end of the treatment period in the CAIFOS trial, the investigators reported fewer cases of heart failure-related deaths with supplemental calcium compared to placebo (160). In another randomized, placebo-controlled trial of calcium and/or vitamin D_3 (RECORD trial), the evaluation of the effect of 1,000 mg/day of calcium (alone or with 800 IU/day of vitamin D) reported no significant increase in the rate of mortality due to vascular disease in 5,292 participants ages 70 years and older (161). A recent cross-sectional analysis of the Third National Health and Nutrition Examination Survey (NHANES III) evaluated the association between calcium intakes and cardiovascular mortality in 18,714 adults with no history of heart disease. No evidence of an association was observed between dietary calcium intake, supplemental calcium intake, or total calcium intake and cardiovascular mortality in either men or women (162).

A few prospective studies have reported positive correlations between high calcium concentrations in the blood and increased rates of cardiovascular events (163, 164). Because supplemental calcium may have a greater effect than dietary calcium on circulating calcium concentrations (see Toxicity), it has been speculated that the use of calcium supplements might promote vascular calcification — a surrogate marker of the burden of atherosclerosis and a major risk factor for cardiovascular events — by raising calcium serum concentrations. In 1,471 older women from the Auckland Calcium Study and 323 healthy older men from another randomized, placebo-controlled trial of daily calcium supplementation (600 mg or 1,200 mg) for two years, serum calcium concentrations were found to be positively correlated with abdominal aortic calcification or coronary artery calcification (165). However, there was no effect of calcium supplementation on measures of vascular calcification scores in men or women. Data from 1,201 participants of the Framingham Offspring study were also used to assess the relationship between calcium intake and vascular calcification. Again, no association was found between coronary calcium scores and total, dietary, or supplemental calcium intake in men or women (166). Nonetheless, in the Multi-Ethnic Study of Atherosclerosis (MESA), a US multicenter prospective study in 6,814 participants followed for a mean 10 years, the greatest risk of developing coronary artery calcification was found in supplement users with the lowest total calcium intake (~306 mg/day of dietary calcium and ~91 mg/day of supplemental calcium), when compared to supplement users with higher total calcium intakes and nonusers (167). Finally, an assessment of atherosclerotic lesions in the carotid artery wall of 1,103 participants in the CAIFOS trial was also conducted after three years of supplementation (168). When compared with placebo, calcium supplementation showed no effect on carotid artery intimal medial thickness (CIMT) and carotid atherosclerosis. Yet, carotid atherosclerosis (but not CIMT) was significantly reduced in women in the highest versus lowest tertile of total (diet and supplements) calcium intakes (≥1,795 mg/day vs. <1,010 mg/day) (168).

The most recent meta-analysis of 18 randomized clinical trials, including a total of 63,563 postmenopausal women, found no evidence of an increased risk for coronary artery disease and all-cause mortality with calcium (≥500 mg/day) supplementation for at least one year (169). Because these clinical trial data are limited to analyses of secondary endpoints, meta-analyses should be interpreted with caution. There is a need for studies designed to examine the effect of calcium supplements on CVD risk as a primary outcome before definite conclusions can be drawn. Based on an updated review of the literature that included four randomized controlled trials, one nested case-control study, and 26 prospective cohort studies (170), the National Osteoporosis Foundation (NOF) and the American Society for Preventive Cardiology (ASPC) concluded that the use of supplemental calcium for generally healthy individuals was safe from a cardiovascular health standpoint when total calcium intakes did not exceed the UL (171). NOF and ASPC support the use of calcium supplements to correct shortfalls in dietary calcium intake and meet current recommendations (171).

Drug interactions

Taking calcium supplements in combination with thiazide diuretics (e.g., hydrochlorothiazide) increases the risk of developing hypercalcemia due to increased reabsorption of calcium in the kidneys. High doses of supplemental calcium could increase the likelihood of abnormal heart rhythms in people taking digoxin (Lanoxin) for heart failure (172). Calcium, when provided intravenously, may decrease the efficacy of calcium channel blockers (173). However, dietary and oral supplemental calcium do not appear to affect the action of calcium channel blockers (174). Calcium may decrease the absorption of tetracycline, quinolone class antibiotics, bisphosphonates, sotalol (a β-blocker), and levothyroxine; therefore, it is advisable to separate doses of these medications and calcium-rich food or supplements by two hours before calcium or four-to-six hours after calcium (175). Supplemental calcium can decrease the concentration of dolutegravir (Tivicay), elvitegravir (Vitekta), and raltegravir (Isentress), three antiretroviral medications, in blood such that patients are advised to take them two hours before or after calcium supplements (175). Intravenous calcium should not be administrated within 48 hours following intravenous ceftriaxone (rocephine), a cephalosporin antibiotic, since a ceftriaxone-calcium salt precipitate can form in the lungs and kidneys and be a cause of death (175). Use of H_2 blockers (e.g., cimetidine) and proton-pump inhibitors (e.g., omeprazole) may decrease the absorption of calcium carbonate and calcium phosphate (reviewed in 176, 177), whereas lithium may increase the risk of hypercalcemia in patients (175). The topical use of calcipotriene, a vitamin D analog, in the treatment of psoriasis places patients at risk of hypercalcemia if they take calcium supplements.

Calcium-nutrient interactions

The presence of calcium decreases iron absorption from nonheme sources (i.e., most supplements and food sources other than meat). However, calcium supplementation up to 12 weeks has not been found to change iron nutritional status, probably due to a compensatory increase in iron absorption (1). Individuals taking iron supplements should take them two hours apart from calcium-rich food or supplements to maximize iron absorption. Although high calcium intakes have not been associated with reduced zinc absorption or zinc nutritional status, an early study in 10 men and women found that 600 mg of calcium consumed with a meal halved the absorption of zinc from that meal (see the article on Zinc) (178). Supplemental calcium (500 mg calcium carbonate) has been found to prevent the absorption of lycopene (a nonprovitamin A carotenoid) from tomato paste in 10 healthy adults randomized into a cross-over study (179).

Linus Pauling Institute Recommendation

The Linus Pauling Institute supports the recommended dietary allowance (RDA) set by the Food and Nutrition Board of the Institute of Medicine. Following these recommendations should provide adequate calcium to promote skeletal health and may also decrease the risks of some chronic diseases.

Children and adolescents (9-18 years)

To promote the attainment of maximal peak bone mass, children and adolescents should consume a total (diet plus supplements) of 1,300 mg/day of calcium.

Adults (women: 19-50 years; men: 19-70 years)

After adult height has been reached, the skeleton continues to accumulate bone until the third decade of life when peak bone mass is attained. To promote the attainment of maximal peak bone mass and to minimize bone loss later in life, adult women (50 years of age and younger) and adult men (70 years of age and younger) should consume a total (diet plus supplements) of 1,000 mg/day of calcium.

Older women (>50 years)

To minimize bone loss, postmenopausal women should consume a total (diet plus supplements) of 1,200 mg/day of calcium. Taking a multivitamin/mineral supplement containing at least 10 μg (400 IU)/day of vitamin D will help to ensure adequate calcium absorption (see the article on Vitamin D).

Older men (>70 years)

To minimize bone loss, older men should consume a total (diet plus supplements) of 1,200 mg/day of calcium. Taking a multivitamin/mineral supplement containing at least 10 μg (400 IU)/day of vitamin D will help to ensure adequate calcium absorption (see the article on Vitamin D).

Pregnant and breast-feeding women

Pregnant and breast-feeding adolescents (<19 years) should consume a total of 1,300 mg/day of calcium, while pregnant and breast-feeding adults (≥19 years) should consume a total of 1,000 mg/day of calcium.

Summary

- Chromium (Cr^{0}) is a ubiquitous trace metal. The predominant chromium form in the body is trivalent chromium (Cr^{3+}), which may potentiate insulin function when provided at pharmacological doses. *(More information)*
- The nutritional essentiality of chromium has been questioned, as a dietary deficiency has not been described. In 2001, the US Institute of Medicine set the adequate intake (AI) of chromium at 20-35 μg/day for adults. However, in 2014 the European Food Safety Authority concluded that requirements for chromium could not be established. *(More information)*
- Results of randomized controlled trials of chromium supplementation in the prevention or treatment of impaired glucose tolerance and type 2 diabetes mellitus have been mixed, with few finding benefits that may be clinically meaningful. *(More information)*
- Evidence that supplemental chromium can help treat metabolic syndrome or polycystic ovary syndrome is largely lacking. *(More information)*
- A well-balanced diet that includes fruit, vegetables, meat, fish, and grains should easily cover dietary needs of chromium. *(More information)*
- Few adverse events have been reported with chromium supplementation. *(More information)*

Chromium was first discovered in 1797. The most stable oxidation state of chromium in biological systems is trivalent chromium (Cr^{3+}), which forms relatively inert complexes with proteins and nucleic acids (1). The essentiality of trivalent chromium is questioned, and its proposed function in the body remains poorly understood. In fact, in 2014 the European Food Safety Authority concluded that a dietary requirement — or even an Adequate Intake — cannot be set for trivalent chromium as no conclusive evidence exists that chromium is essential at any dietary intake (2). Trivalent chromium appears to have health effects only at pharmacological doses (reviewed in 3), and a dietary deficiency of the mineral has not been observed.

Another common and stable form of chromium in the environment is hexavalent chromium (Cr^{6+}). Hexavalent chromium is derived from trivalent chromium by heating at alkaline pH and is used as a source of chromium for industrial purposes. Hexavalent chromium is highly toxic and is classified as a human carcinogen when inhaled (4). In the acidic environment of the stomach, hexavalent chromium can be readily reduced to trivalent chromium by reducing substances present in food, which limits the ingestion of hexavalent chromium (5-7).

Function

Trivalent chromium has been proposed to be the cofactor for a biologically active molecule that could enhance the effects of insulin on target tissues. Insulin is secreted by specialized cells in the pancreas in response to increased blood glucose concentration, such as after a meal. Insulin binds to insulin receptors on the surface of cells, activating the receptors and stimulating glucose uptake by cells. Through its interaction with insulin receptors, insulin provides cells with glucose for energy and helps maintain blood glucose within a narrow range of concentrations. In addition to its effects on carbohydrate (glucose) metabolism, insulin also influences the metabolism of fat and protein (8). Together, a decreased response to insulin or decreased insulin sensitivity in peripheral tissues (adipose tissue, muscle, and liver) and a progressive defect in insulin secretion may result in impaired glucose tolerance, frequently leading to overt type 2 diabetes mellitus. The body initially increases the secretion of insulin by specialized pancreatic cells to overcome the decrease in insulin sensitivity. However, the pancreas eventually fails to produce enough insulin to maintain normal blood glucose concentrations. Individuals with type 2 diabetes are at increased risk for cardiovascular disease (9).

Possible mechanism of action

The precise composition and structure of the biologically active form of chromium is not known. One model postulates that trivalent chromium might be the cofactor of a low-molecular-weight chromium-binding substance known as LMWCr or chromodulin (10). Chromodulin has been shown to play a role in the transport of chromium from the tissues to the bloodstream for ultimate elimination in the urine (11). When chromium is consumed at high levels, such as from dietary supplements, levels of chromodulin in tissues rise. At these high levels, chromodulin is proposed to enhance the cascade of signaling events induced by the binding of insulin to extracellular α-subunit of the insulin receptor (IR) (12). Upon insulin binding, the tyrosine kinase domain of the intracellular β-subunit of the IR becomes activated and causes the phosphorylation of tyrosine residues in the β-subunit itself. Subsequently, IR activation triggers a series of rapid phosphorylation reactions that activate many downstream effectors, eventually resulting in an increase in glucose uptake and storage (10). While this model is supported by *in vitro* studies, this mode of action for chromodulin has not been confirmed to date by *in vivo* studies.

Some, but not all, studies conducted in cell-based and animal models of insulin resistance and diabetes mellitus have found that chromium inhibits the activity of protein tyrosine phosphatase-1B (PTP-1B) and other negative regulators of insulin signaling, suggesting that chromium might improve insulin sensitivity under insulin-resistant conditions (reviewed in 10). A study in diabetic mice also suggested that chromium may reduce insulin clearance and enhance insulin signaling by inhibiting the proteolysis (degradation) of insulin and some downstream effectors (13). Additional mechanisms that may underlie the effect of chromium on insulin sensitivity, such as the reduction of markers of oxidative stress and inflammation known to contribute to insulin resistance, are under investigation (reviewed in 10, 14).

Nutrient interactions

Iron

Chromium competes for one of the binding sites on the iron transport protein, transferrin. However, supplementation of older men with 925 μg/day of chromium for 12 weeks did not significantly affect measures of iron nutritional status (15). A study of younger men found an insignificant decrease in transferrin saturation with iron after supplementation of 200 μg/day of chromium for eight weeks, but no long-term studies have addressed this issue (16). In a 12-week, randomized controlled trial, supplementation with chromium picolinate (200 μg/day) did not affect iron nutritional status in premenopausal women when compared to picolinic acid or placebo (17). Iron overload in hereditary hemochromatosis may interfere with chromium transport by competing for transferrin binding. It has been hypothesized that decreased chromium transport might contribute to the pathogenesis of diabetes mellitus in patients with hereditary hemochromatosis (5).

Vitamin C

Chromium uptake is enhanced in animals when given at the same time as vitamin C (7). In a study of three women, administration of 100 mg of vitamin C together with 1 mg of chromium resulted in higher plasma levels of chromium than 1 mg of chromium without vitamin C (5).

Carbohydrates

Compared to diets rich in complex carbohydrates (e.g., whole grains), diets high in simple sugars (e.g., sucrose) result in increased urinary chromium excretion in adults. This effect may be related to increased insulin secretion in response to the consumption of simple sugars compared to complex carbohydrates (5).

Deficiency

Dietary chromium deficiency has not been observed in humans. Potential cases of chromium deficiency were thought to have been observed in a few patients on long-term intravenous feeding (parenteral nutrition) who did not receive supplemental chromium in their intravenous solutions. The subjects developed abnormal glucose utilization and increased insulin requirements that responded to chromium supplementation (18). However, because intravenous solutions provide chromium at doses well above dietary levels, it has been suggested that chromium might produce biological effects only at pharmacological doses (3, 14). However, the differences in symptoms among subjects, the range of doses of chromium utilized over varying windows of time, and the different reported outcomes are now realized to make interpretation of these results difficult, even in terms of any potential pharmacological effects from the chromium supplementation. Because chromium appeared to enhance the action of insulin and chromium deficiency has been proposed to result in impaired glucose tolerance, chromium insufficiency has been hypothesized to be a contributing factor to the development of type 2 diabetes mellitus (5, 19). However, evidence for this is ambiguous at best.

Urinary chromium loss was reportedly increased by endurance exercise in male runners, suggesting that chromium needs may be greater in individuals who exercise regularly (20). In one study, weightlifting (resistive exercise) was found to increase urinary excretion of chromium in older men. However, chromium absorption also increased, leading to little or no net loss of chromium as a result of resistive exercise (21).

The absence of animal models for chromium deficiency makes it difficult to study possible biochemical, physiological, and functional abnormalities associated with inadequate intakes of chromium (if chromium is nutritionally essential) (2).

The Adequate Intake (AI)

Because there was not enough information to set an estimated average requirement (EAR), the Food and Nutrition Board (FNB) of the US Institute of Medicine (now the National Academy of Medicine) established an adequate intake (AI) based on the chromium content in healthy diets (**Table 1**; 5).

Table 1. Adequate Intake (AI) for Chromium

Life Stage	Age	Males (μg/day)	Females (μg/day)
Infants	0-6 months	0.2	0.2
Infants	7-12 months	5.5	5.5
Children	1-3 years	11	11
Children	4-8 years	15	15
Children	9-13 years	25	21
Adolescents	14-18 years	35	24
Adults	19-50 years	35	25
Adults	51 years and older	30	20
Pregnancy	18 years and younger	-	29

Pregnancy	19 years and older	-	30
Breast-feeding	18 years and younger	-	44
Breast-feeding	19 years and older	-	45

The case of trivalent chromium essentiality has been questioned in both animals and humans in the last decades, and in 2014 the European Food Safety Authority's Panel on Dietetic Products, Nutrition, and Allergies — which provides dietary guidelines for the EU community — concluded that requirements for chromium could not be established (2). The FNB, which sets dietary intake recommendations for the United States and Canada, is not currently reconsidering the AI level for chromium (22).

Disease Prevention

Impaired glucose tolerance and type 2 diabetes mellitus

Early controlled studies in subjects with impaired glucose tolerance reported that chromium supplementation improved some measure of glucose utilization or had beneficial effects on blood lipid profiles (23). Impaired glucose tolerance refers to a prediabetic state and is currently defined by the presence of impaired fasting glucose (fasting plasma glucose concentration of 100-125 mg/dL) and impaired glucose tolerance status (plasma glucose concentration of 140-199 mg/dL during a two-hour challenge test with a 75-g oral glucose load) (24). Impaired glucose tolerance is associated with modest increases in risk of cardiovascular disease, as well as other traditional microvascular complications of diabetes mellitus (25). Current estimates suggest that up to 70% of individuals with impaired glucose tolerance eventually develop type 2 diabetes (26).

In a randomized, double-blind, placebo-controlled study in 56 subjects at risk of developing type 2 diabetes, six months of daily chromium picolinate supplementation (500 μg or 1,000 μg) had no effect on glucose and insulin concentrations, insulin sensitivity, and blood lipid profiles (27). Another randomized, placebo-controlled trial in 31 individuals without diabetes reported a great variability in serum and urinary chromium concentrations in response to a daily supplementation with 1,000 μg of chromium picolinate for 16 weeks. Also, in the chromium-supplemented group, participants with higher *vs.* lower serum chromium concentrations (>3.1 μg/L *vs.* ≤3.1 μg/L) exhibited a decline in insulin sensitivity that could not be explained by expression changes in the genes involved in insulin signaling (28). Additionally, a meta-analysis of nine randomized clinical trials published between 1992 and 2010 reported that chromium at doses of 200-1,000 μg/day for 8-16 weeks had no effect on fasting glucose concentrations in 309 individuals without diabetes (29).

Cardiovascular disease

Impaired glucose tolerance and type 2 diabetes mellitus are associated with adverse changes in lipid profiles and increased risk of cardiovascular disease. Studies examining the effects of chromium supplementation on lipid profiles have given inconsistent results. While some studies have observed reductions in serum total cholesterol, LDL-cholesterol, and triglyceride levels or increases in HDL-cholesterol levels, others have observed no effect. Such mixed responses of lipid and lipoprotein levels to chromium supplementation may reflect differences in chromium nutritional status. It is possible that only individuals with insufficient dietary intake of chromium will experience beneficial effects on lipid profiles after chromium supplementation (6, 7, 30).

Moreover, a recent meta-analysis of 10 randomized controlled trials, mostly in patients with type 2 diabetes mellitus or metabolic syndrome, found chromium supplementation had no effect on either systolic or diastolic blood pressure (31). Yet, another meta-analysis of randomized controlled trials found chromium supplementation decreased circulating levels of two proinflammatory biomarkers associated with increased cardiovascular risk, hs-CRP and TNF-α, but not blood levels of IL-6 (32).

Health claims

Increases muscle mass

Claims that chromium supplementation increases lean body mass and decreases body fat are based on the relationship between chromium and insulin action (see Function). In addition to regulating glucose metabolism, insulin is known to affect fat and protein metabolism (8). At least 12 placebo-controlled studies have compared the effect of chromium supplementation (172-1,000 μg/day of chromium as chromium picolinate) with or without an exercise program on lean body mass and measures of body fat (reviewed in 33). In general, the studies that used the most sensitive and accurate methods of measuring body fat and lean mass (dual energy x-ray absorbtiometry or DEXA and hydrodensitometry or underwater weighing) did not find a beneficial effect of chromium supplementation on body composition (6, 30). In the US, the claim that chromium picolinate increases lean body mass is not allowed on supplement labels because it is not substantiated by the available research (34, 35).

Promotes weight loss

Controlled studies of chromium supplementation have demonstrated little if any beneficial effect on weight or fat loss, and claims of weight loss in humans appear to be exaggerated. In 1996, the US Federal Trade Commission (FTC) ruled that there was no scientific basis for claims that chromium picolinate could promote weight loss and fat loss in humans (36). A 2013 meta-analysis of 11 randomized, double-blind, placebo-controlled trials in 866 overweight or obese subjects found a significant 0.50-kilogram (1.10-pound) reduction in body weight with supplemental chromium (most exclusively in the form of chromium picolinate) at doses between 137 μg/day and 1,000 μg/day for 8 to 24 weeks (37). However, such a small change did not reach a clinically significant weight loss of ≥5% of the initial body weight (38). A 2019 meta-analysis of 19 clinical trials found similar results: chromium supplementation at doses between 20 μg/day and 1,000 μg/day for 4 to 24 weeks decreased body weight in overweight or obese subjects by only 0.75 kg, a clinically insignificant amount (39). Some reports have suggested that supplemental chromium may reduce food craving and intake in overweight or obese women (40, 41). Yet, current available data remain insufficient to support the use of chromium supplements as a weight-loss strategy (42). In the US, the claim that chromium picolinate promotes weight loss is not allowed on supplement labels because it is unsubstantiated (34, 35).

Reduces insulin resistance

Despite stating that scientific evidence is severely limited, the US FDA allows a single claim on supplement labels: "One small study suggests that chromium picolinate may reduce the risk of insulin resistance, and therefore possibly may reduce the risk of type 2 diabetes. FDA concludes, however, that the existence of such a relationship between chromium picolinate and either insulin resistance or type 2 diabetes is highly uncertain." (35, 43).

Disease Treatment

Type 2 diabetes mellitus

Type 2 diabetes mellitus is characterized by chronic hyperglycemia (elevated blood glucose concentration) and insulin resistance. Because resistance to insulin is usually associated with a compensatory rise in insulin secretion, circulating insulin concentrations in people with type 2 diabetes may be higher than in healthy individuals. Yet, the resistance of peripheral tissues (especially liver and skeletal muscle) to insulin also implies that the physiological effects of insulin are reduced.

Since cell culture and rodent models of diabetes have implicated chromium in the regulation of insulin sensitivity and blood glucose levels, the relationship between chromium nutritional status and type 2 diabetes mellitus has generated considerable scientific interest. Early reports observed that individuals with overt type 2 diabetes for over two years had higher rates of urinary chromium loss than healthy individuals (44). Small, well-designed studies of chromium supplementation in individuals with type 2 diabetes showed no improvement in blood glucose control, although they provided some evidence of reduced insulin concentrations and improved blood lipid profiles (45). In 1997, the results of a placebo-controlled trial conducted in China indicated that chromium supplementation might be beneficial in the treatment of type 2 diabetes (46). One hundred and eighty participants were randomized to receive either a placebo or chromium supplements in the form of chromium picolinate at either 200 μg/day or 1,000 μg/day. After four months of treatment, fasting blood glucose concentrations were found to be 15% to 19% lower in those who took 1,000 μg/day of chromium compared to those who took the placebo. Yet, blood glucose concentrations in those taking 200 μg/day of chromium did not differ significantly from those who took placebo. Chromium picolinate at either 200 μg/day or 1,000 μg/day was also associated with reduced insulin concentrations compared to placebo. The level of glycated hemoglobin A1c (HbA1c), a measure of glycemic control over the past four months, was also significantly reduced in both chromium-supplemented groups. However, a number of limitations made it difficult to extrapolate the results to the US population (47). Besides, the study was excluded from meta-analyses of randomized controlled trials due to insufficient data quality (29, 48).

In a recent systematic review and meta-analysis of randomized controlled trials in patients with type 2 diabetes, chromium supplementation (50-1,000 μg/day for 4 to 25 weeks) reduced concentrations of fasting plasma glucose (23 trials) and insulin (14 trials), and improved HbA1c values (18 trials) (49). These effects were not dose dependent (49). Yet, other meta-analyses in patients with type 2 diabetes did not find significant benefits of chromium supplementation on fasting glucose and insulin (50) or HbA1C (51). Moreover, a systematic review on 20 randomized controlled trials found that only a handful of chromium supplementation studies resulted in glycemic changes that are considered clinically meaningful, i.e., consistent with treatment goals of a 7.2-mmol/dL decrease in fasting glucose, a decrease of 0.5% in HbA1c, or reaching ≤7% HbA1c (52).

Gestational diabetes

Few studies have examined the effects of chromium supplementation on gestational diabetes mellitus, a condition that is estimated to affect 5.8% to 9.2% of pregnant women in the US (53). The occurrence of gestational diabetes during pregnancy is associated with insufficient insulin secretion and glucose intolerance of variable severity (54). Peripheral insulin resistance usually increases in the second or third trimester of pregnancy. Because elevated maternal blood glucose concentrations can have adverse effects on the developing fetus, women with gestational diabetes are at increased risk of pregnancy complications (55). After delivery, impaired glucose tolerance generally reverts to normal glucose tolerance. However, nearly one-third of women who have had gestational diabetes develop postpartum glucose intolerance (prediabetes or type 2 diabetes) (56, 57). The question also arises as to whether low chromium levels might be an effect rather than a contributing factor in gestational diabetes.

An observational study in pregnant women did not find serum chromium levels to be associated with measures of glucose tolerance or insulin resistance in late pregnancy (58). However, it is not known whether measures of serum chromium levels truly reflect tissue chromium levels and chromium status during pregnancy. A more recent prospective study following 425 pregnant women also failed to find a correlation between serum chromium concentrations and incidence of gestational diabetes (59). A cross-sectional study of 90 pregnant women in southern India found that those with gestational diabetes had significantly lower serum chromium concentrations compared to gestational diabetes-free women. Given the above mixed results, it should be noted that different methods were used to measure circulating chromium concentrations in each study. Also, it is possible that nutritional chromium status may vary among ethnically distinct populations so that studies including pregnant women from different ethnic backgrounds and/or geographical areas would give different results.

In addition, there is currently insufficient evidence to evaluate the effect of supplemental chromium on gestational diabetes. Women with gestational diabetes whose diets were supplemented with 4 μg of chromium per kilogram of body weight daily as chromium picolinate for eight weeks had decreased fasting blood glucose and insulin concentrations compared to those who took a placebo. Yet, insulin therapy rather than chromium picolinate was required to normalize severely elevated blood glucose levels (6, 60).

Metabolic syndrome

Metabolic syndrome is a combination of medical conditions, including hypertension, dyslipidemia, central obesity, and insulin resistance, that places one at increased risk for cardiovascular disease and type 2 diabetes mellitus (see the page: Metabolic Syndrome). A prospective cohort study that followed 3,648 young US adults for 23 years found an inverse association between toenail chromium concentration measured at baseline and risk of developing metabolic syndrome (61). An inverse association between plasma chromium concentration and metabolic syndrome was also observed in a case-control study in 4,282 Chinese adults (62). However, low toenail and plasma chromium may be the result of metabolic syndrome, rather than suggesting a cause or contributing factor.

Only a few randomized controlled trials have examined whether chromium supplementation might benefit patients with metabolic syndrome. In a randomized, double-blind, placebo-controlled trial in 65 patients with metabolic syndrome, 300 μg/day of supplemental chromium (from chromium-enriched yeast) for 24 weeks had no effect on measured parameters of glucose, insulin, and lipid metabolism (63). While large-scale trials would be needed, there is presently no evidence that chromium can help treat metabolic syndrome.

Polycystic ovary syndrome

Polycystic ovary syndrome (PCOS) is a common endocrine disorder affecting women of childbearing age, with an estimated worldwide prevalence of 21% (64). The disorder has a multifactorial etiology and is characterized by menstrual irregularities, polycystic ovaries, and infertility. Similar to metabolic syndrome, women with PCOS often have various metabolic abnormalities, including dyslipidemia, obesity (especially abdominal obesity), impaired glucose tolerance, insulin resistance, and are at increased risk for developing type 2 diabetes mellitus (65).

Several randomized controlled trials have evaluated whether chromium supplementation might help treat PCOS, but the results are conflicting. A 2017 systematic review and meta-analysis of seven clinical trials found that chromium picolinate supplementation (of either 200 μg/day or 1,000 ug/day) for 8 to 24 weeks decreased BMI (3 studies), lowered free testosterone concentration (5 studies), and decreased fasting serum insulin concentration (5 studies) but had no effect on concentrations of fasting blood glucose (4 studies), total testosterone (3 studies), luteinizing hormone (3 studies), or follicle-stimulating hormone (2 studies) (66). However, other recent systematic reviews and meta-analyses have concluded that chromium supplementation in women with PCOS does not result in significant or clinically meaningful health benefits, including with respect to glucose and insulin metabolism (67-69).

Sources

Food sources

The amount of chromium in food is variable and has been measured accurately in relatively few foods. Presently, there is no large database for the chromium content of food. Whole-grain products, high-bran cereals, green beans, broccoli, nuts, and egg yolk are good sources of chromium. Processed meats may also be high in chromium, depending on the processing equipment and method (70). Foods high in simple sugars, such as sucrose and fructose, are usually low in chromium and may actually promote chromium excretion (6, 71). Estimated average chromium intakes in the US range from 23 μg/day-29 μg/day for adult women and 39-54 μg/day for adult men (5). The chromium content of some foods is listed in **Table 2** and expressed in micrograms (μg) (72). Since chromium content varies significantly between different batches of the same food, the information provided in the table should serve only as a guide to the chromium content of food.

Table 2. Some Food Sources of Chromium

Food	Serving	Chromium (μg)
Broccoli	½ cup	11.0
Green beans	½ cup	1.1
Potatoes (mashed)	1 cup	2.7
Grape juice	8 fl. ounces	7.5
Orange juice	8 fl. ounces	2.2
Beef	3 ounces	2.0
Turkey breast	3 ounces	1.7
Turkey ham (processed)	3 ounces	10.4
Waffle	1 (~2.5 ounces)	6.7
Bagel	1	2.5
English muffin	1	3.6
Apple w/ peel	1 medium	1.4
Banana	1 medium	1.0

Supplements

Trivalent chromium is available as a supplement in several forms, including chromium chloride, chromium nicotinate, chromium picolinate, and high-chromium yeast. These are available as stand-alone supplements or in combination products, including multivitamin/mineral supplements. Doses typically range from 100 to 300 μg of elemental chromium in single-nutrient supplements and from 10 to 180 μg in multivitamin/mineral supplements (73).

Much of the research on impaired glucose tolerance and type 2 diabetes mellitus uses chromium picolinate as the source of chromium, although investigations suggest that its bioavailability may not be greater than that of dietary chromium (74). Some concerns have been raised over the long-term safety of chromium picolinate supplementation (see Safety).

Safety

Toxicity

Hexavalent chromium (chromium VI; Cr^{6+}) is a recognized carcinogen, with inhalation causing lung, nasal, and sinus cancers (75). Exposure to hexavalent chromium in dust has been associated with an increased incidence of lung cancer and is known to cause inflammation of the skin (dermatitis).

In contrast, there is little evidence that trivalent chromium (chromium III; Cr3+) is toxic to humans. The toxicity from oral intakes is considered to be low because ingested chromium is poorly absorbed, and most absorbed chromium is rapidly excreted in the urine (76). Because no adverse effects have been convincingly associated with excess intake of trivalent chromium from food or supplements, the Food and Nutrition Board (FNB) of the Institute of Medicine (now the National Academy of Medicine) did not set a tolerable upper intake level (UL) for chromium. Yet, despite limited evidence for adverse effects, the FNB acknowledged the possibility of a negative impact of high oral intakes of supplemental trivalent chromium on health and advised caution (5).

Chromium picolinate

Most of the concerns regarding the long-term safety of trivalent chromium supplementation arise from several studies in cell culture, suggesting trivalent chromium, especially in the form of chromium picolinate, may increase DNA damage (77-80). A study in 10 women taking 400 μg/day of chromium as chromium picolinate found no evidence of increased oxidative damage to DNA as measured by antibodies to an oxidized DNA base (81).

Many studies have demonstrated the safety of daily doses of up to 1,000 μg of chromium for several months (46, 82). However, there have been a few isolated reports of serious adverse reactions to chromium picolinate. Kidney failure was reported five months after a six-week course of 600 μg/day of chromium in the form of chromium picolinate (83), while kidney failure and impaired liver function were reported after the use of 1,200 to 2,400 μg/day of chromium in the form of chromium picolinate over a period of four to five months (84). Additionally, a 24-year old healthy male reportedly developed reversible, acute renal failure after taking chromium picolinate-containing supplements for two weeks (85). Individuals with pre-existing kidney or liver disease may be at increased risk of adverse effects and should limit supplemental chromium intake (5).

Drug interactions

Little is known about drug interactions with chromium in humans. Large doses of calcium carbonate or magnesium hydroxide-containing antacids decreased chromium absorption in rats. In contrast, non-steroidal anti-inflammatory drugs, aspirin and indomethacin, can increase chromium absorption in rats (7).

Linus Pauling Institute Recommendation

The lack of any known indicators of chromium nutritional status in humans makes it difficult to determine the level of chromium intake most likely to promote optimum health, if such exists. Following the Linus Pauling Institute recommendation to take a multivitamin/mineral supplement containing 100% of the daily values (DV) of most nutrients may provide 10 to 180 μg/day of chromium, which is generally considered safe.

Older adults (>50 years)

Although the requirement for chromium is not known to be higher for older adults, one study found that chromium concentrations in hair, sweat, and urine decreased with age (86). Following the Linus Pauling Institute recommendation to take a multivitamin/mineral supplement containing 100% of the daily values (DV) of most nutrients should provide sufficient chromium for older adults.

Because impaired glucose tolerance, type 2 diabetes mellitus, and metabolic syndrome are associated with serious health problems, individuals with any of these conditions should seek medical advice if considering the use of high-dose chromium supplements.

Summary

- Copper is an essential cofactor for oxidation-reduction reactions involving copper-containing oxidases. Copper enzymes regulate various physiologic pathways, such as energy production, iron metabolism, connective tissue maturation, and neurotransmission. *(More information)*
- Copper deficiency can result from malnutrition, malabsorption, or excessive zinc intake and can be acquired or inherited. Symptoms include deficiencies in blood cells, bone and connective tissue abnormalities, and neurologic disorders. *(More information)*
- Marginal copper imbalance has been linked to impaired immune function, bone demineralization, and increased risk of cardiovascular and neurodegenerative diseases. However, the use of more precise indicators of nutritional copper status needs to be considered for future research. *(More information)*
- Organ meats, shellfish, nuts, seeds, wheat-bran cereals, and whole-grain products are good sources of copper. *(More information)*
- Copper toxicity is rare and often associated with genetic defects of copper metabolism. *(More information)*

Copper (Cu) is an essential trace element for humans and animals. In the body, copper shifts between the cuprous (Cu^{1+}) and cupric (Cu^{2+}) forms, though the majority of the body's copper is in the Cu^{2+} form. The ability of copper to easily accept and donate electrons explains its important role in oxidation-reduction (redox) reactions and in scavenging free radicals (1). Although Hippocrates is said to have prescribed copper compounds to treat diseases as early as 400 B.C. (2), scientists are still uncovering new information regarding the functions of copper in the human body (3).

Function

Copper is a critical functional component of several essential enzymes known as cuproenzymes (4). Some of the physiologic functions known to be copper-dependent are discussed below.

Energy production

The copper-dependent enzyme, cytochrome *c* oxidase, plays a critical role in cellular energy production. By catalyzing the reduction of molecular oxygen (O_2) to water (H_2O), cytochrome *c* oxidase generates an electrical gradient used by the mitochondria to create the vital energy-storing molecule, ATP (5).

Connective tissue formation

Another cuproenzyme, lysyl oxidase, is required for the cross-linking of collagen and elastin, which are essential for the formation of strong and flexible connective tissue. The action of lysyl oxidase helps maintain the integrity of connective tissue in the heart and blood vessels and also plays a role in bone formation (2).

Iron metabolism

Four copper-containing enzymes, known as multi-copper oxidases (MCO) or ferroxidases, have the capacity to oxidize ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}), the form of iron that can be loaded onto the protein transferrin for transport to the site of red blood cell formation. The MCO family comprises the circulating ceruloplasmin (which represents ~90% of plasma copper), the membrane-bound ceruloplasmin (called GPI-ceruloplasmin), and two proteins called Hephaestin and Zyklopen found in the intestine and the placenta, respectively (6). Interestingly, mice that do not express ceruloplasmin ($Cp^{-/-}$) have normal copper metabolism but abnormal iron accumulation in the liver (7, 8). Similarly, individuals lacking ceruloplasmin display iron overload in selected tissues, including liver, brain, and retina (9). This supports the idea that the ferroxidase activity of ceruloplasmin is essential to the flux of iron in the body. Moreover, the fact that iron mobilization from storage sites is impaired in copper deficiency supports the role of MCO in iron metabolism (10).

Central nervous system

A number of reactions essential to normal function of the brain and nervous system are catalyzed by cuproenzymes.

Neurotransmitter synthesis

Dopamine β-hydroxylase catalyzes the conversion of dopamine to the neurotransmitter, norepinephrine (11).

Formation and maintenance of myelin

The myelin sheath is made of phospholipids whose synthesis depends on cytochrome *c* oxidase activity (2).

Melanin formation

The cuproenzyme, tyrosinase, is required for the formation of the pigment melanin. Melanin is formed in cells called melanocytes and plays a role in the pigmentation of the hair, skin, and eyes (2).

Antioxidant functions

Superoxide dismutase

Superoxide dismutase (SOD) functions as an antioxidant by catalyzing the conversion of superoxide radicals (free radicals or ROS) to hydrogen peroxide, which can subsequently be reduced to water by other antioxidant enzymes (12). Two forms of SOD contain copper: (1) copper/zinc SOD is found within most cells of the body, including red blood cells; and (2) extracellular SOD is a copper-containing enzyme found at high levels in the lungs and low levels in plasma (2).

Ceruloplasmin

Ceruloplasmin may function as an antioxidant in two different ways. Free copper and iron ions are powerful catalysts of free-radical damage. By binding copper, ceruloplasmin prevents free copper ions from catalyzing oxidative damage. The ferroxidase activity of ceruloplasmin (oxidation of ferrous iron) facilitates iron loading onto its transport protein, transferrin, and may prevent free ferrous ions (Fe^{2+}) from participating in harmful free-radical-generating reactions (12).

Regulation of gene expression

Cellular copper levels may affect the synthesis of proteins by enhancing or inhibiting the transcription of specific genes. Copper may regulate the expression of genes by increasing the level of intracellular oxidative stress. A number of signal transduction pathways are activated in response to oxidative stress and can lead to an increase in the expression of genes involved in the detoxification of reactive oxygen species (13).

Nutrient interactions

Iron

Adequate copper nutritional status is necessary for normal iron metabolism and red blood cell formation. Anemia is a clinical sign of copper deficiency, and iron has been found to accumulate in the livers of copper-deficient animals, indicating that copper (via the copper-containing ceruloplasmin) is required for iron transport to the bone marrow for red blood cell formation (see Iron metabolism) (2). The connection between copper availability and iron metabolism has also been established in humans; copper deficiency can lead to secondary ceruloplasmin deficiency and hepatic iron overload and/or cirrhosis (10). Oral copper supplementation restored normal ceruloplasmin levels and plasma ferroxidase activity and corrected the iron-metabolism disorder in a copper-deficient subject (14). Moreover, infants fed a high iron formula absorbed less copper than infants fed a low iron formula, suggesting that high iron intakes may interfere with copper absorption in infants (15).

Zinc

High supplemental zinc intakes of 50 mg/day or more for extended periods of time may result in copper deficiency. High dietary zinc intakes increase the synthesis of an intestinal cell protein called metallothionein, which binds certain metals and prevents their absorption by trapping them in intestinal cells. Metallothionein has a stronger affinity for copper than zinc, so high levels of metallothionein induced by excess zinc cause a decrease in copper absorption. In contrast, high copper intakes have not been found to affect zinc nutritional status (2, 15). Zinc supplementation (10 mg/day for eight weeks) was able to restore normal plasma copper/zinc ratios in 65 subjects on long-term hemodialysis who initially exhibited low zinc levels and elevated copper levels. Whether improving zinc and copper status of hemodialysis patients can impact their clinical outcomes needs to be assessed (16).

Fructose

High fructose diets have exacerbated copper deficiency in rats but not in pigs whose gastrointestinal systems are more like those of humans. Very high levels of dietary fructose (20% of total calories) did not result in copper depletion in humans, suggesting that fructose intake does not result in copper depletion at levels relevant to normal diets (2, 15).

Vitamin C

Although vitamin C supplements have produced copper deficiency in guinea pigs (17), the effect of vitamin C supplements on copper nutritional status in humans is less clear. Two small studies in healthy, young adult men indicate that the oxidase activity of ceruloplasmin may be impaired by relatively high doses of supplemental vitamin C. In one study, vitamin C supplementation of 1,500 mg/day for two months resulted in a significant decline in ceruloplasmin oxidase activity (18). In the other study, supplements of 605 mg/day of vitamin C for three weeks resulted in decreased ceruloplasmin oxidase activity, although copper absorption did not decline (19). Neither of these studies found vitamin C supplementation to adversely affect copper nutritional status.

Deficiency

Clinically evident or frank dietary copper deficiency is relatively uncommon. Serum copper and ceruloplasmin levels may fall to 30% of normal in cases of severe copper deficiency. Hypocupremia (low copper content in blood) is also observed in genetic disorders of copper metabolism, such as aceruloplasminemia and, paradoxically, in Wilson's disease, which are not linked to dietary copper deficiency. One of the most common clinical signs of copper deficiency is an anemia that is unresponsive to iron therapy but corrected by copper supplementation. Although the anemia is thought to result from defective iron mobilization due to decreased ceruloplasmin activity, the absence of ceruloplasmin in individuals with inherited aceruloplasminemia is not always associated with overt anemia (20). Copper deficiency may also lead to abnormally low numbers of white blood cells known as neutrophils (neutropenia), a condition that may be accompanied by increased susceptibility to infection. Copper depletion studies have suggested that reduced copper availability might affect erythroid and myeloid cell lineage, supporting a role for copper in the regulation of blood cell renewal (21, 22). More research is clearly needed to uncover the mechanisms underlying copper deficiency-induced anemia and neutropenia (4, 23). Osteoporosis and other abnormalities of bone development related to copper deficiency are most common in copper-deficient, low-birth-weight infants and young children. Less common features of copper deficiency may include loss of pigmentation, neurological symptoms, and impaired growth (2, 5).

Individuals at risk of deficiency

Cow's milk is relatively low in copper, and cases of copper deficiency have been reported in high-risk infants and children fed only cow's milk formula (24). High-risk individuals include premature infants (especially low-birth-weight infants); infants with prolonged diarrhea; infants and children recovering from malnutrition; and individuals with malabsorption syndromes, including celiac disease, sprue, and short bowel syndrome due to surgical removal of large portions of the intestine. Individuals receiving intravenous total parenteral nutrition lacking copper or other restricted diets may also require supplementation with copper and other trace elements (2, 5). Copper deficiency in infants with cholestasis (reduced biliary excretion of copper) has been linked to long-term parenteral nutrition lacking copper (25). Case reports indicate that cystic fibrosis patients may also be at increased risk of copper insufficiency (26). Finally, excessive zinc intake has led to secondary copper deficiency in individuals using zinc supplements or zinc-enriched dental creams (27, 28).

Acquired copper deficiency

A neurologic syndrome has been described in adults with acquired copper deficiency (29). The symptoms include central nervous system demyelination, polyneuropathy, myelopathy, and inflammation of the optic nerve. The etiology is unknown in absence of prominent risk factors (see Individuals at risk of deficiency); case reports describe increased intestinal copper content suggesting a malabsorption syndrome like Menkes disease, but mutations in *ATP7A* gene were not linked to the condition (30) (see Inherited copper deficiency). Oral copper replacement (2 mg/day of elemental copper) normalizes serum copper and ceruloplasmin concentrations, stabilizes the condition, and significantly improves the quality of life of affected subjects. However, the duration of copper supplementation has not yet been established, and dosing increments might be required in cases of relapse (29).

Inherited copper deficiency

Copper trafficking within most cells except hepatocytes (liver cells) is facilitated by a Cu^{1+}-transporting ATPase called ATP7A. Mutations in the *ATP7A* gene impair the transport of intracellular copper, which accumulates in the cytosol of enterocytes and vascular endothelial cells (31). This results in systemic copper deficiency and decreased cuproenzyme activity. Copper transport into the brain is also affected, leading to copper accumulation in the blood-brain barrier and reduced cuproenzyme activity in neurons. Affected individuals are diagnosed with Menkes disease (MD) or with a milder form of the disease called occipital horn syndrome (OHS). The clinical features of MD include intractable seizures, connective tissue disorders, subdural hemorrhage, and hair abnormalities ("kinky hair"). OHS patients exhibit muscular hypotonia and connective tissue abnormalities, including exostosis on occipital bones. Subcutaneous injections of copper-histidine are used to bypass the defective intestinal absorption and improve copper metabolic function in patients. However, copper entry into the brain remains limited (reviewed in 32).

The Recommended Dietary Allowance (RDA)

A variety of indicators were used to establish the RDA for copper, including plasma copper concentration, serum ceruloplasmin activity, superoxide dismutase activity in red blood cells, and platelet copper concentration (15). The RDA for copper reflects the results of depletion-repletion studies and is based on the prevention of deficiency (**Table 1**).

Table 1. Recommended Dietary Allowance (RDA) for Copper

Life Stage	Age	Males (μg/day)	Females (μg/day)
Infants	0-6 months	200 (AI)	200 (AI)
Infants	7-12 months	220 (AI)	220 (AI)
Children	1-3 years	340	340
Children	4-8 years	440	440
Children	9-13 years	700	700
Adolescents	14-18 years	890	890
Adults	19 years and older	900	900
Pregnancy	all ages	-	1,000
Breast-feeding	all ages	-	1,300

Disease Prevention

Cardiovascular disease

While it is clear that severe copper deficiency results in heart abnormalities and damage (cardiomyopathy) in some animal species, the pathology differs from atherosclerotic cardiovascular disease that is prevalent in humans (15). Studies in humans have produced inconsistent results, and their interpretation is hindered by the lack of a reliable marker of copper nutritional status. Outside the body, free copper is known to be a pro-oxidant and is frequently used to produce oxidation of low-density lipoprotein (LDL) in the test tube. The copper-containing protein ceruloplasmin has been found to stimulate LDL oxidation in the test tube (33), leading some scientists to propose that increased copper levels could increase the risk of atherosclerosis by promoting the oxidation of LDL. However, there is little evidence that copper or ceruloplasmin promotes LDL oxidation in the human body. Additionally, the cuproenzymes, superoxide dismutase and ceruloplasmin, are known to have antioxidant properties, leading some experts to propose that copper deficiency rather than excess copper increases the risk of cardiovascular disease (34).

Epidemiological studies

Several epidemiological studies have found increased serum copper levels to be associated with increased risk of cardiovascular disease. A prospective cohort study in the US examined serum copper levels in more than 4,500 men and women 30 years of age and older (35). During the following 16 years, 151 participants died from coronary heart disease (CHD). After adjusting for other risk factors of heart disease, those with serum copper levels in the two highest quartiles had a significantly greater risk of dying from CHD. Three other case-control studies conducted in Europe had similar findings. One small study in 60 patients with chronic heart failure or ischemic heart disease reported that serum copper was a predictor of short-term outcome (36). Another prospective cohort study in 4,035 middle-aged men reported that high serum copper levels were significantly related to a 50% increase in all-cause mortality; however, serum copper was not significantly associated with cardiovascular mortality in this study (37). Additionally, serum copper has been found to be elevated in patients with rheumatic heart disease (38).

It is important to note that serum copper largely reflects serum ceruloplasmin and is not a sensitive indicator of copper nutritional status (39). Serum ceruloplasmin levels are known to increase by 50% or more under certain conditions of physical stress, such as trauma, inflammation, or disease. Because over 90% of serum copper is carried in ceruloplasmin, which is increased in many inflammatory conditions, elevated serum copper may simply be a marker of inflammation that accompanies atherosclerosis. In contrast to the epidemiological findings linking increased serum copper levels to heart disease, two autopsy studies found copper levels in heart muscle were actually lower in patients who died of CHD than those who died of other causes (40). Additionally, the copper content of white blood cells has been positively correlated with the degree of patency of coronary arteries in CHD patients (41, 42). Further, patients with a history of myocardial infarction (MI) had lower concentrations of extracellular superoxide dismutase (SOD) than those without a history of MI (43). Thus, due to a lack of a reliable biomarker of copper nutritional status, it is not clear whether copper is related to cardiovascular disease.

Intervention studies

While studies in very small numbers of adults fed experimental diets low in copper have demonstrated adverse changes in blood cholesterol levels, including increased total and LDL-cholesterol levels and decreased HDL-cholesterol levels (44), other studies have not confirmed those results (45). Copper supplementation of 2-3 mg/day for four to eight weeks did not result in clinically significant changes in cholesterol levels (34, 46, 47). Further, research has failed to find evidence that increased copper intake increases oxidative stress. In a multi-center, placebo-controlled trial, copper supplementation of 3 or 6 mg/day for six weeks did not result in increased susceptibility of LDL to oxidation induced outside the body (*ex vivo*) by copper or peroxynitrite (a reactive nitrogen species) (48). Moreover, supplementation with 3 or 6 mg/day of copper decreased the *in vitro* oxidizability of red blood cells (49), indicating that relatively high intakes of copper do not increase the susceptibility of LDL or red blood cells to oxidation.

Summary

Although free copper and ceruloplasmin can promote LDL oxidation in the test tube, there is little evidence that increased dietary copper increases oxidative stress in the human body. Increased serum copper levels have been associated with increased cardiovascular disease risk, but the significance of these findings is unclear due to the association between serum ceruloplasmin levels and inflammatory conditions. Clarification of the relationships between copper nutritional status, ceruloplasmin levels, and cardiovascular disease risk requires further research.

Notably, it was suggested that elevated plasma copper concentrations could be linked to high homocysteine levels in individuals with vascular diseases (50, 51). Increased levels of homocysteine are associated with arterial wall lesions and increased risk of cardiovascular disease (52). The interaction between homocysteine and copper was linked to impaired vascular endothelial function in animal models (53, 54). However, although copper restriction in animals has shown some beneficial effects on homocysteine levels and atherogenic lesions (55, 56), it is not known whether copper imbalance contributes to the atherogenic effect of homocysteine in humans.

Immune system function

Copper is known to play an important role in the development and maintenance of immune system function, but the exact mechanism of its action is not yet known. Neutropenia (abnormally low numbers of white blood cells called neutrophils) is a clinical sign of copper deficiency in humans. Adverse effects of insufficient copper on immune function appear most pronounced in infants. Infants with Menkes disease, a genetic disorder that results in severe copper deficiency, suffer from frequent and severe infections (57, 58). In a study of 11 malnourished infants with evidence of copper deficiency, the ability of certain white blood cells to engulf pathogens increased significantly after one month of copper supplementation (59). Moreover, 11 men on a low-copper diet (0.66 mg copper/day for 24 days and 0.38 mg/day for another 40 days) showed a decreased proliferation response when white blood cells, called monocytes, were isolated from their blood and presented with an immune challenge in cell culture (60). Recent mechanistic studies support a role for copper in innate immune response against bacterial infections (reviewed in 61). While severe copper deficiency has adverse effects on immune function, the effects of marginal copper insufficiency in humans are not yet clear.

Osteoporosis

The progressive loss of bone mineral density (BMD) leading to osteopenia (pre-osteoporosis) and osteoporosis is commonly observed in the elderly population. Women are more often affected by osteoporosis than men, (e.g., prevalence ratio is 5:1 in non-Hispanic whites) (62), primarily due to the postmenopausal reduction in estrogen production that is essential for maintaining strength of muscle, bone, and connective tissue (63). Osteoporosis is associated with an increased risk of falls, bone fracture, and mortality in individuals over 65 years of age (64). Osteoporosis has also been reported in infants with severe copper deficiency (65, 66), but it is not clear whether marginal copper deficiency during adulthood contributes to osteoporosis. While an increase in bone resorption (breakdown) was observed in 11 healthy adult males with a marginal copper intake of 0.7 mg/day for six weeks (67), the supplementation of 3 to 6 mg/day of copper for six weeks had no effect on biochemical markers of bone resorption or bone formation in two studies of healthy adult men and women (68, 69). However, it is possible that a reduction in copper intake and absorption in older people reduces the activity of the copper-dependent enzyme, lysyl oxidase, which is required for the maturation (cross-linking) of collagen—a key element in the organic matrix of bone.

Overall, research regarding the role of copper nutritional status in age-related osteoporosis is limited. An early study found that serum copper levels in 46 elderly patients with hip fractures were significantly lower than those of matched controls (70). However, another study found no differences in serum copper levels among postmenopausal women with normal BMD (N=40), osteopenia (N=40), or osteoporosis (N=40) (71). A small study in perimenopausal women, who consumed an average of 1 mg of dietary copper daily, reported decreased loss of BMD from the lumbar spine after copper supplementation of 3 mg/day for two years (72). Additionally, a two-year double-blind, placebo-controlled trial in 59 postmenopausal women found that a combination of supplemental calcium and trace minerals, including 2.5 mg of copper daily, resulted in maintenance of spinal bone density, whereas supplemental calcium or trace minerals, alone, were not effective in preventing loss of bone density (73). However, a more recent randomized, double-blind, placebo-controlled study, which initially enrolled 224 healthy, postmenopausal women aged 51 to 80 years, found daily supplementation with 600 mg of calcium, 2 mg of copper, and 12 mg of zinc for two years decreased whole-body BMD compared to supplemental calcium alone. Moreover, although BMD was clearly reduced in subjects with dietary copper intakes below the RDA (0.9 mg/day), supplemental copper did not prevent the progressive loss of BMD as well as the calcium regimen alone (74). Finally, several studies have suggested that tooth loss might be related to poor systemic BMD (75, 76). When compared with 20 healthy-matched controls, 50 patients (mean age 47.5 years) with low spinal BMD and advanced tooth wear were found with significantly lower copper content in tooth enamel. However, despite evidence suggesting bone demineralization, the serum copper levels in this population were similar to those of the healthy group (77). More research is required to draw conclusions regarding the effects of marginal copper deficiency and copper supplementation on bone metabolism and age-related osteoporosis.

Neurodegenerative diseases

Alzheimer's disease

Cognitive deterioration in individuals with Alzheimer's disease (AD) is linked to the presence of β-amyloid plaques and abnormal Tau protein-forming aggregates. The possibility that copper imbalance is involved in the onset of AD is currently investigated. First, it appears that the fraction of 'free' copper (not bound to ceruloplasmin) is augmented in copper homeostasis disorders, as well as in AD individuals (78, 79). Moreover, AD patients appear to have higher levels of serum copper compared to healthy controls (80). Among the many hypotheses supporting a role for copper in AD onset or progression, it is suggested that copper could be involved in the formation of senile plaques through hypermetallation of the β-amyloid peptides, possibly leading to zinc depletion, enhanced oxidative stress, and even brain damage (81, 82). Recent research has also identified genetic variations (polymorphisms) in the ATP7B gene that may modify the risk of developing AD (83). The protein, ATP7B, is responsible for the excretion of hepatic copper into the biliary tract, and its impairment in Wilson's disease results in increased 'free' copper level in blood and copper accumulation in liver and brain.

More research is needed to investigate whether genetic variants could influence the susceptibility of environmental exposure to high levels of copper. The addition of copper to drinking water has been associated with enhanced pathologic features in animal models of AD (84, 85). One study in a rabbit model reported that combining a high-cholesterol diet and copper (0.12 mg/L in drinking water) could impair cognition (84). A prospective cohort study in 3,718 elderly participants of the Chicago Health and Aging Project, followed for 5.5 years, evaluated the impact of fat and copper intakes using food frequency questionnaires and various cognitive assessments. For individuals with high intakes of saturated and *trans* fat, cognitive decline was greater for those in the highest quintile of total copper intake compared to the lowest quintile (median intake of 2.75 vs. 0.88 mg/day) (86).

Although a dysfunctional copper metabolism is suggested as a risk factor for AD, it could also be symptomatic of the disease. Moreover, it is still unclear whether copper supplementation or restriction could delay the progression of AD. A small, double-blind, placebo-controlled trial in 68 individuals with mild AD found that supplementation of 8 mg/day of copper for one year delayed the decrease of the β-amyloid peptide Aβ42 in cerebrospinal fluid; a decrease in Aβ42 has been linked to cognitive deterioration (87). However, this delay was not associated with improved cognitive performance (88). Based on the utilization of copper-chelating agents in Wilson's disease, the recent use of slow-release zinc acetate (150 mg/day for six months) in a randomized, placebo-controlled study of 60 patients with mild to moderate AD resulted in a decrease in serum 'free' copper and stabilization of cognition deficits (81). Additional human studies are needed to clarify the role of copper in AD onset and progression, and to evaluate whether dietary copper might help prevent AD in high-risk individuals or manage the disease in AD patients.

Parkinson's disease

Both neurologically presenting Wilson's disease and inherited aceruloplasminemia are characterized by copper accumulation in the brain, resulting in neurologic symptoms (dystonia and cognitive impairment) that resemble Parkinson's disease (PD) (89). The level of copper is diminished in brain regions of neuronal loss in PD patients (90). However, the recent meta-analysis of studies measuring copper levels in serum, plasma, and cerebrospinal fluid did not find any difference between PD patients and healthy elderly subjects (91).

Sources

Food sources

Copper is found in a wide variety of foods and is most plentiful in organ meats, shellfish, nuts, and seeds. Wheat-bran cereals and whole-grain products are also good sources of copper. According to national surveys, the average dietary intake of copper in the US is approximately 1.0 to 1.1 mg (1,000 to 1,100 μg) per day for adult women and 1.2 to 1.6 mg (1,200 to 1,600 μg) per day for adult men (15). The copper content of some foods that are relatively rich in copper is listed in micrograms (μg) in **Table 2**. For more information on the nutrient content of foods, search USDA's FoodData Central.

Table 2. Some Food Sources of Copper

Food	Serving	Copper (μg)
Liver (beef), cooked, pan-fried	1 ounce	4,128
Mollusks, oysters, eastern, wild, cooked, moist heat	6 medium oysters	2,397

Mollusks, oysters, eastern, wild, cooked, moist heat	6 medium oysters	2,397
Crab meat, Alaskan king, cooked	3 ounces	1,005
Crab meat, blue, cooked, moist heat	3 ounces	692
Mollusks, clams, mixed species, cooked, moist heat	3 ounces	585
Cashews nuts, raw	1 ounce	622
Sunflower seed kernels, dry roasted	1 ounce	519
Hazelnuts, dry roasted	1 ounce	496
Almonds	1 ounce	292
Peanut butter, chunk style, without salt	2 tablespoons	185
Lentils, mature seeds, cooked, boiled, without salt	1 cup	497
Mushrooms, white, raw	1 cup (sliced)	223
Shredded wheat cereal	2 biscuits	167
Chocolate (semisweet)	1 ounce	198

Supplements

Copper supplements are available as cupric oxide, copper gluconate, copper sulfate, and copper amino acid chelates (92).

Safety

Toxicity

Copper toxicity is rare in the general population. Acute copper poisoning has occurred through the contamination of beverages by storage in copper-containing containers, as well as from contaminated water supplies (93). Guideline values for copper in drinking water have been set by the US Environmental Protection Agency (1.3 mg/liter) and by the World Health Organization (2 mg/liter) (94). Symptoms of acute copper toxicity include abdominal pain, nausea, vomiting, and diarrhea; such symptoms help prevent additional ingestion and absorption of copper. More serious signs of acute copper toxicity include severe liver damage, kidney failure, coma, and death. Of more concern from a nutritional standpoint is the possibility of liver damage resulting from long-term exposure to lower doses of copper. In generally healthy individuals, doses of up to 10,000 μg (10 mg) daily have not resulted in liver damage. For this reason, the US Food and Nutrition Board set the tolerable upper intake level (UL) for copper at 10 mg/day from food and supplements (15; **Table 3**). It should be noted that individuals with genetic disorders affecting copper metabolism (e.g., Wilson's disease, Indian childhood cirrhosis, and idiopathic copper toxicosis) may be at risk for adverse effects of chronic copper toxicity at significantly lower intake levels. There is some concern that the UL of 10 mg/day might be too high. In particular, men in a research study consumed 7.8 mg/day of copper for 147 days. They accumulated copper during that time, and some indices of immune function and antioxidant status suggested that these functions were adversely affected by the high intakes of copper (95, 96). However, another study did not report any adverse effects in individuals supplemented with 8 mg/day of copper for six months (88).

Table 3. Tolerable Upper Intake Level (UL) for Copper

Age Group	UL (μg/day)
Infants 0-12 months	Not possible to establish*
Children 1-3 years	1,000
Children 4-8 years	3,000
Children 9-13 years	5,000
Adolescents 14-18 years	8,000
Adults 19 years and older	10,000
*Source of intake should be from food and formula only.	

Drug interactions

Relatively little is known about the interaction of copper with drugs. Penicillamine is used to bind copper and enhance its elimination in Wilson's disease, a genetic disorder resulting in hepatic copper overload. Because penicillamine dramatically increases the urinary excretion of copper, individuals taking the medication for reasons other than copper overload may have an increased copper requirement.

Linus Pauling Institute Recommendation

The RDA for copper (900 μg/day for adults) is sufficient to prevent deficiency, but the lack of clear indicators of copper nutritional status in humans makes it difficult to determine the level of copper intake most likely to promote optimum health or prevent chronic disease. A varied diet should provide enough copper for most people. For those who are concerned that their diet may not provide adequate copper, a multivitamin/mineral supplement will generally provide at least the RDA for copper.

Older adults (>50 years)

Because aging has not been associated with significant changes in the requirement for copper, our recommendation for older adults is the same as that for adults 50 and younger (97).

Summary

- Fluoride is the ionic form of the naturally occurring fluorine element. The anion increases the structural stability of teeth and bones through interactions with calcium phosphates. *(More information)*
- The daily intake recommendations for fluoride are based on the safest and most effective intakes to prevent dental caries. *(More information)*
- The use of fluoridated dental products and adequate intakes of fluoride reduce the occurrence of caries throughout life by promoting tooth mineralization and re-mineralization. Large randomized, placebo-controlled studies are needed to evaluate whether the topical application of fluoridated agents could also prevent dental erosion. *(More information)*
- Epidemiological and clinical evidence is currently limited to support a role for water fluoridation in the prevention of osteoporosis and bone fracture. *(More information)*
- Therapeutic trials have found a dose-dependent effect of fluoride on fracture risk in osteoporotic patients. However, the occurrence of numerous side effects warrants additional studies to guarantee that safe and effective doses can be used alone or in combination with current therapies. *(More information)*
- The major sources of systemic and topical fluoride are drinking water, foods and beverages made with fluoridated water, infant formulas, and fluoride-containing oral care products. Fluoridated salt and milk are currently available outside the US in Europe, Latin America, and Southeast Asia. *(More information)*
- While increased exposure to fluoride has led to a decline in dental caries, the prevalence of white speckling or mottling of the permanent teeth, known as dental fluorosis, has increased. Bone tissue homeostasis may also be affected by excess fluoride intake. *(More information)*

Fluorine occurs naturally as the negatively charged ion, fluoride (F^-). Fluoride is considered a trace element because only small amounts are present in the body (about 2.6 grams in adults), and because the daily requirement for maintaining dental health is only a few milligrams a day. About 95% of the total body fluoride is found in bones and teeth (1). Although its role in the prevention of dental caries (tooth decay) is well established, fluoride is not generally considered an essential mineral element because humans do not require it for growth or to sustain life (2). However, if one considers the prevention of chronic disease (dental caries) an important criterion in determining essentiality, then fluoride might well be considered an essential trace element (3).

Function

Fluoride is absorbed in the stomach and small intestine. Once in the bloodstream it rapidly enters mineralized tissue (bones and developing teeth). At usual intake levels, fluoride does not accumulate in soft tissue. The predominant mineral elements in bone are crystals of calcium and phosphate, known as hydroxyapatite crystals. Fluoride's high chemical reactivity and small radius allow it to either displace the larger hydroxyl (-OH) ion in the hydroxyapatite crystal, forming fluoroapatite, or to increase crystal density by entering spaces within the hydroxyapatite crystal. Fluoroapatite hardens tooth enamel and stabilizes bone mineral (4).

Nutrient interactions

Both calcium and magnesium form insoluble complexes with fluoride and are capable of significantly decreasing fluoride absorption when present in the same meal. However, the absorption of fluoride in the form of monofluorophosphate (unlike sodium fluoride) is unaffected by calcium. Also, a diet low in chloride (salt) has been found to increase fluoride retention by reducing urinary excretion of fluoride (1).

Deficiency

In humans, the only clear effect of inadequate fluoride intake is an increased risk of dental caries (tooth decay) for individuals of all ages. Epidemiological investigations of patterns of water consumption and the prevalence of dental caries across various US regions with different water fluoride concentrations led to the development of a recommended optimum range of fluoride concentration of 0.7-1.2 milligrams/liter (mg/L) or parts per million (ppm); the lower concentration was recommended for warmer climates where water consumption is higher, and the higher concentration was recommended for colder climates. In 2015, the US Department of Health and Human Services recommended that all community water systems adjust the fluoride concentration to 0.7 mg/L, as more recent studies did find a relationship between water intake and outdoor air temperature. This recommendation was made in an effort to reduce the risk of dental fluorosis (see below) and in light of the widespread availability of fluoride from other sources, including fluoride-containing oral-care products (5). A number of studies conducted prior to the introduction of fluoride-containing toothpastes demonstrated that the prevalence of dental caries was 40% to 60% lower in communities with optimal water fluoride concentrations than in communities with low water fluoride concentrations (6).

The Adequate Intake (AI)

The Food and Nutrition Board (FNB) of the US Institute of Medicine updated its recommendations for fluoride intake in 1997. Because data were insufficient to establish a Recommended Dietary Allowance (RDA), Adequate Intake (AI) levels were set based on estimated intakes that have been shown to reduce the occurrence of dental caries most effectively without causing the unwanted side effect of tooth enamel mottling known as dental fluorosis (0.05 mg/kg of body weight) (**Table 1**; 6). See the section below on Safety for a discussion of dental fluorosis.

Table 1. Adequate Intake (AI) for Fluoride

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	0.01	0.01
Infants	7-12 months	0.5	0.5
Children	1-3 years	0.7	0.7
Children	4-8 years	1.0	1.0
Children	9-13 years	2.0	2.0
Adolescents	14-18 years	3.0	3.0
Adults	19 years and older	4.0	3.0
Pregnancy	all ages	-	3.0
Breast-feeding	all ages	-	3.0

Disease Prevention

Dental caries (cavities and tooth decay)

Specific cariogenic (cavity-causing) bacteria (mainly *Streptococcus mutans* and *Streptococcus sobrinus*) found in dental plaque are capable of metabolizing fermentable carbohydrates (sugars) and converting them to organic acids that can dissolve sensitive tooth enamel. If unchecked, the bacteria may penetrate deeper layers of the tooth and progress into the soft pulp tissue at the center. Untreated caries can lead to severe pain, local infection, tooth loss or extraction, nutritional problems, and serious systemic infections in susceptible individuals (7). Dental caries — both treated and untreated — contribute to diminished overall oral health, which, in turn, may affect systemic health. For example, some observational studies have suggested a link between systemic inflammation in individuals with periodontal (gum) infection and insulin resistance (8), type 2 diabetes mellitus (9), hypertension (10), and coronary heart disease (11). Moreover, the bacterium causing periodontitis, *Porphyromonas gingivalis*, may be linked to rheumatoid arthritis (12, 13). Poor oral health in general may constitute a risk factor for coronary heart disease (14) and other cardiovascular diseases (15, 16).

Systemic effects of fluoride on teeth

Increased fluoride exposure, most commonly through community water fluoridation, has been found to decrease the incidence of dental caries in children and adults (17, 18). Between 1976 and 1987, clinical studies in several countries demonstrated that the addition of fluoride to community water supplies (0.7-1.2 ppm) reduced caries by 30%-60% in primary (baby) teeth and 15%-35% in permanent teeth (19). A 2015 review and meta-analysis of prospective observational studies found a 35% and 26% reduction in number of decayed, missing, and filled primary and permanent teeth with consumption of fluoridated versus non-fluoridated water, respectively (20). While fluoride's prevention of dental caries is primarily through topical action, fluoride consumed in water appears to have a systemic effect in children before all teeth have erupted — typically through 12 years of age.

Fluoride is incorporated into the developing enamel of teeth and increases the resistance to caries. Since the caries preventative effect of fluoride is also topical (surface) in children after teeth have erupted and in adults, the optimal protection achieved by fluoridated water likely occurs through both systemic exposure before and after tooth eruption and topical exposure after tooth eruption.

Topical effects of fluoride on teeth

Research has indicated that the primary action of fluoride occurs topically after the teeth erupt into the mouth. Ingested fluoride is secreted in the saliva and contributes to topical protection. When enamel is partially demineralized by organic acids, fluoride in the saliva can enhance the remineralization of enamel through its interactions with calcium and phosphate. Fluoride containing remineralized enamel is more resistant to acid attack and demineralization. In salivary concentrations associated with optimum fluoride intake, fluoride has been found to inhibit bacterial enzymes, resulting in reduced acid production by cariogenic bacteria (7, 17).

The use of topically applied fluoride-containing products, including toothpaste, gel, varnish, and mouth rinse, is thought to have contributed to the substantial decrease in the prevalence of caries over the last decades (21). A 2013 meta-analysis of fluoride interventions in children and adolescents (up to 16 years of age) found that the application of fluoride varnish for at least one year was associated with a 37% reduction in decayed, missing, and filled tooth surfaces in decayed tooth surfaces of primary teeth; the anti-caries effect on the permanent teeth corresponded to a 43% decrease compared to no treatment or placebo (22). A recent (2021) meta-analysis of topical fluoride reviewed 15 clinical trials with 9,541 participants. Specifically, the meta-analysis evaluated 14 trials of fluoride varnish compared to placebo or no fluoride and one trial of fluoride foam, and found that topical fluoride reduced dental caries increment by about one tooth surface over a two-year period (23). The same meta-analysis also found that fluoride varnish significantly prevented any incident dental caries, but only for children who were younger than 2 years of age (23).

The effects of fluoride-containing toothpaste has been more extensive. A 2017 meta-analysis of 96 randomized controlled trials, including more than 65,000 participants, found tooth brushing with a fluoridated toothpaste reduced caries in primary teeth of children and in permanent teeth of adults compared to brushing with non-fluoridated toothpaste (24). In participants overall, use of toothpastes containing 1,000 to 1,500 ppm of fluoride had a caries-preventative effect compared to use of toothpastes with lower fluoride concentrations or with non-fluoridated toothpastes (24). A systematic review of 17 clinical trials found use of fluoridated toothpaste effectively reduced dental caries in primary teeth of children younger than 6 years who were at high risk of developing dental caries (25).

Dental erosion (tooth wear)

The attack of dental hard tissue by acids other than those produced by the bacterial plaque may lead to the loss of tooth enamel, also known as dental erosion. Factors involved in dental erosion include acidic foods and beverages (e.g., carbonated drinks) and acid reflux (26). The protective effect of fluoridated agents against dental erosion has mainly been observed in *in vitro* studies (reviewed in 26). Nevertheless, a meta-analysis of four small, randomized trials examining the effect of fluoride in toothpaste, varnish, and saliva on dental erosion did not find any overall benefit compared to placebo (27). Larger clinical studies are needed to evaluate whether topical fluoride applications can prevent dental erosion and/or reduce the progression of existing erosive lesions.

Osteoporosis

Although fluoride in pharmacologic doses has been shown to be a potent therapeutic agent for increasing spinal bone mass (see Disease Treatment), there is little evidence that water fluoridation at optimum levels for the prevention of dental caries is helpful in the prevention of osteoporosis. The majority of studies conducted to date have failed to find clinically significant differences in bone mineral density (BMD) or fracture incidence when comparing residents of areas with fluoridated water supplies to residents in areas without fluoridated water supplies (28, 29). However, two studies found that drinking water fluoridation was associated with decreased incidence of hip fracture in the elderly. In addition, one study in Italy found a significantly greater risk of femoral (hip) fractures in men and women residing in an area with low water fluoridation (0.05 ppm) compared to the risk in a similar population whose water supply was naturally fluoridated (1.45 ppm) at higher than optimum levels for prevention of dental caries (30). Another study in Germany found no significant difference in BMD between residents of a community whose water supply had been optimally fluoridated for 30 years (1 ppm) compared with those who resided in a community without fluoridated water. However, this study reported that the incidence of hip fracture in men and women, aged 85 years or older, was significantly lower in the community with fluoridated water compared to the community with non-fluoridated water, despite higher calcium levels in the non-fluoridated water supply (31). Another community-based study in 1,300 women found that elevated serum fluoride concentrations were not related to BMD or to osteoporotic fracture incidence (32). Finally, a nationwide cohort study in Sweden found no association between chronic exposure to fluoridated water and incidence of hip fracture (33). A 2015 meta-analysis, which pooled results of 13 prospective cohort studies and one case-control study, found that fluoride exposure in drinking water was not associated with risk of hip fracture (34).

Moreover, because bone mineral accretion early in life affects risk for osteoporosis in later adulthood, studies have examined the association of fluoride intake during adolescence and bone outcomes. Reports from the Iowa Bone Development Study, an ongoing prospective cohort study, indicate little to no association of fluoride intake during childhood and adolescence with measures of bone microstructure throughout adolescence (35-37) and into early adulthood (38).

Disease Treatment

Osteoporosis

Osteoporosis is characterized by decreased bone mineral density (BMD) and increased bone fragility and susceptibility to fracture. In general, decreased BMD is associated with increased risk of fracture. However, the usual relationship between BMD and fracture risk does not always hold true when very high (pharmacologic) doses of fluoride are used to treat osteoporosis. Most available therapies for osteoporosis (e.g., estrogen, calcitonin, and bisphosphonates) decrease bone loss (resorption), resulting in very small increases in BMD. Pharmacologic doses of fluoride are capable of producing large increases in the BMD of the lumbar spine. Overall, therapeutic trials of fluoride in patients with osteoporosis have not consistently demonstrated significant decreases in the occurrence of vertebral fracture despite dramatic increases in lumbar spine BMD (39). A meta-analysis of 11 controlled studies, including 1,429 participants, found that fluoride treatment resulted in increased BMD at the lumbar spine but was not associated with a lower risk of vertebral fractures (40). This meta-analysis also found that higher concentrations of fluoride were associated with increased risk of non-vertebral fractures after four years of treatment. Early studies using high doses of fluoride (>20 mg/day) may have induced rapid bone mineralization in the absence of adequate calcium and vitamin D, resulting in denser bones that were not mechanically stronger (41, 42). Analysis of bone architecture has also shed some light on the inconsistent effect of fluoride therapy in reducing vertebral fractures. Research has indicated that osteoporosis may be associated with an irreversible change in the architecture of bone known as decreased trabecular connectivity. Normal bone consists of a series of plates interconnected by thick rods. Severely osteoporotic bone has fewer plates, and the rods may be fractured or disconnected (decreased trabecular connectivity) (43). Despite fluoride therapy increasing bone density, it probably cannot reduce bone resorption and restore connectivity in patients with severe bone loss. Thus, fluoride therapy may be less effective in osteoporotic individuals who have already lost substantial trabecular connectivity (39, 44).

On the other hand, randomized controlled trials using lower fluoride doses (≤20 mg/day), intermittent dosage schedules, or slow-release formulations (enteric coated sodium fluoride) have demonstrated a decreased incidence of vertebral and non-vertebral fractures along with increased bone density of the lumbar spine (45). Yet, bone biopsies from postmenopausal, osteoporotic women treated with 20 mg/day of fluoride showed evidence of abnormal bone mineralization despite calcium and vitamin D supplementation (46). Additionally, a randomized, double-blind, placebo-controlled study did not find any increase in lumbar spine BMD in 180 postmenopausal women with osteopenia (early osteoporosis) who were given daily supplements of up to 10 mg/day of fluoride for one year (47). Additional studies are required to assess whether a safe dose of fluoride can be found to maximize bone formation while preventing mineralization defects.

Safety of fluoride therapy for osteoporosis

Serious side effects have been associated with the high doses of fluoride used to treat osteoporosis (45). They include gastrointestinal irritation, joint pain in the lower extremities, and the development of calcium deficiency and stress fractures. The reasons for the occurrence of lower extremity joint pain and stress fractures in patients taking fluoride for osteoporosis remain unclear, but they may be related to rapid increases in bone formation without sufficient calcium to support such an increase (39). Presently, enteric coated sodium fluoride or monofluorophosphate preparations offer a lower side effect profile than the high-dose sodium fluoride used in earlier trials. Additionally, sufficient calcium and vitamin D must be provided to support fluoride-induced bone formation. Although fluoride therapy may be beneficial for the treatment of osteoporosis in appropriately selected and closely monitored individuals, uncertainty about its safety and benefit in reducing fractures has kept the US Food and Drug Administration (FDA) from approving fluoride therapy for osteoporosis (48). Combinations of lower doses of fluoride with antiresorptive agents, such as estrogen or bisphosphonates, may improve therapeutic results while minimizing side effects (49, 50). Yet, randomized studies have shown that the risk of fractures remained unchanged whether treatments include fluoride, antiresorptives, or both (45, 46). Additional studies are warranted to determine whether any treatment combinations could provide substantial therapeutic benefits over monotherapy.

Sources

Water fluoridation

The major source of dietary fluoride in the US diet is drinking water. Controlled addition of fluoride to water is used by communities as a public health measure to adjust fluoride concentration in drinking water to prevent dental caries. Originally, an optimal range of 0.7 to 1.2 milligrams (mg) per liter (corresponding to 0.7-1.2 ppm) was established, which was shown to decrease the incidence of dental caries while minimizing the risk of dental fluorosis and other adverse effects. In 2015, the US Department of Health and Human Services recommended that the optimal concentration in drinking water be set at 0.7 ppm (see Safety) (51). Approximately 73% of the US population receives water with sufficient fluoride for the prevention of dental caries (52). The average fluoride intake for adults living in fluoridated communities ranges from 1.4 to 3.4 mg/day compared to 0.3 to 1 mg/day in non-fluoridated areas (6). Since well water can vary greatly in its fluoride content, people who consume water from wells should have the fluoride content of their water tested by their local water district or health department. Water fluoride testing may also be warranted in households that use home water treatment systems. While water softeners are not thought to change water fluoride levels, reverse osmosis systems, distillation units, and some water filters have been found to remove significant amounts of fluoride from water. However, Brita-type carbon-charcoal filters do not remove fluoride (6, 48).

Bottled water sales have grown exponentially in the US in the last decades, and studies have found that most bottled waters contain sub-optimal levels of fluoride, although there is considerable variation (53). For example, a study of 105 different bottled water products in the Greater Houston metropolitan area found that over 80% had fluoride concentrations of less than 0.4 ppm; only 5% of the tested products had fluoride concentrations within the recommended range (54). Several other studies have reported similar findings, with most bottled waters relatively low in fluoride, but a few in the optimal range or higher (55-57). The FDA-approved claim that "drinking fluoridated water may reduce the risk of tooth decay" is only used by bottlers when the water contains greater than 0.6 ppm of fluoride but no more than 1.0 ppm of fluoride. However, bottlers are not required to provide the fluoride concentration in bottled water unless fluoride was added (58).

Infant formulas

While consumption of fluoride from water presents very little risk of adverse effects in adults except in extreme circumstances (see Safety), consumption of relatively large amounts of water mixed with formula concentrates appears to increase the risk for the development of dental fluorosis in infants (59-61). One study found that, on average, at least half of all fluoride ingested by infants 6 months and younger was from water mixed with formula concentrates (62). The study of 49 commercially available infant formulas in the Chicago area showed that milk-based ready-to-feed, liquid concentrate, and powdered formulas (reconstituted with deionized water) had mean fluoride concentrations of 0.15 ppm, 0.27 ppm, and 0.12 ppm, respectively (63). Fluoride content was significantly higher in soy-based compared to milk-based liquid concentrate formulas (0.50 ppm vs. 0.27 ppm). Using average body weights and total formula intakes during the first year of life, the authors estimated that the risk of exceeding the tolerable upper intake level (UL) for fluoride ingestion was minimal when liquid concentrate and powdered formulas were reconstituted with water containing less than 0.5 ppm of fluoride, but the risk was maximal with 1.0 ppm fluoridated water. Fluoride-free or low-fluoride water labeled as "deionized," "purified," "demineralized," "distilled," or "produced through reverse-osmosis" can be used in order to minimize the risk for mild fluorosis (58). However, infants between 6 and 12 months may not reach the adequate intake of fluoride if they are fed ready-to-feed formulas or formulas reconstituted with water containing less than 0.4 ppm (63).

For additional information on fluoride and infant formulas, see the CDC website.

Food and beverage sources

The fluoride content of most foods is low (less than 0.05 mg/100 grams or 0.5 ppm). Rich sources of fluoride include tea, which concentrates fluoride in its leaves, and marine fish that are consumed with their bones (e.g., sardines). Foods made with mechanically separated (boned) chicken, such as canned meats, hot dogs, and infant foods, also add fluoride to the diet (64). In addition, certain fruit juices, particularly grape juices, often have relatively high fluoride concentrations (65). Foods generally contribute only 0.3-0.6 mg of the daily intake of fluoride. An adult male residing in a community with fluoridated water has an intake range from 1 mg/day-3 mg/day. Intake is less than 1 mg/day in non-fluoridated areas (2). **Table 2** provides a range of fluoride content for a few fluoride-rich foods. For more information on the fluoride content of foods and beverages, search the USDA national fluoride database.

Table 2. Some Food Sources of Fluoride

Food	Serving	Fluoride (mg)	Fluoride (ppm)*
Black tea	100 mL (3.5 fluid ounces)	0.25-0.39	2.5-3.9
Fruit juice	100 mL (3.5 fluid ounces)	0.02-0.21	0.2-2.1
Crab (canned)	100 g (3.5 ounces)	0.21	2.1
Rice (cooked)	100 g (3.5 ounces)	0.04	0.4
Fish (cooked)	100 g (3.5 ounces)	0.02	0.2
Chicken	100 g (3.5 ounces)	0.015	0.15
*1.0 part per million (ppm) = 1 milligram/liter (mg/L)			

Fluoride supplements

Fluoride supplements — available only by prescription in the US — are intended for infants 6 months and older and children up to 16 years of age living in areas with suboptimal water fluoridation for the purpose of bringing their intake to approximately 1 mg/day (6). The American Dental Association Council on Scientific Affairs recommends the prescription of fluoride supplements only to children at high risk of developing dental caries (66). The supplemental fluoride dosage schedule in **Table 3** was recommended by the American Dental Association, the American Academy of Pediatric Dentistry, and the American Academy of Pediatrics (66, 67). It requires knowledge of the fluoride concentration of local drinking water, as well as other possible sources of fluoride intake. For more detailed information regarding fluoride and the prevention of dental caries, visit the American Dental Association website.

Table 3. American Dental Association Fluoride Supplement Schedule

Age	Fluoride Ion Level in Drinking Water (ppm)*		
	<0.3 ppm	0.3-0.6 ppm	>0.6 ppm
Birth - 6 months	None	None	None
6 months - 3 years	0.25 mg/day**	None	None
3 years - 6 years	0.50 mg/day	0.25 mg/day	None
6 years - 16 years	1.0 mg/day	0.50 mg/day	None
*1.0 part per million (ppm) = 1 milligram/liter (mg/L) **2.2 mg sodium fluoride contains 1 mg fluoride ion.			

Toothpaste

Fluoridated toothpastes (1,000-1,100 ppm of fluoride) are very effective in preventing dental caries but also add considerably to fluoride intake of children, especially young children who are more likely to swallow toothpaste. Researchers estimate that children under 6 years of age may ingest an average of 0.3 mg of fluoride from toothpaste with each brushing. Children under the age of 6 years who ingest more than two or three times the recommended fluoride intake are at increased risk of a white speckling or mottling of the permanent teeth, known as dental fluorosis (see Safety section below). A major source of excess fluoride intake in this age group comes from swallowing fluoride-containing toothpaste. To prevent dental fluorosis while providing optimum protection from tooth decay, it is recommended that parents supervise children under 6 years of age while brushing with fluoridated toothpaste. In addition to discouraging the swallowing of toothpaste, children should be supervised during teeth brushing, and young children should be encouraged to use very small amounts of toothpaste — a "smear amount" (a thin layer of toothpaste that covers less than half of the bristle surface of a child-size toothbrush; size equivalent to a grain of rice) for children younger than 3 years, and no more than a pea-sized application of toothpaste for children 3 to 6 years of age (25, 68-70). Interestingly, it has been suggested that the management of the fluorosis risk in young children who ingest fluoridated toothpaste could include the use of toothpaste formulation that reduces gastrointestinal absorption and bioavailability of fluoride (71).

Salt fluoridation

Fluoridation of salt has been implemented in several countries worldwide as an alternative to water fluoridation to promote the ingestion of fluoride and improve oral care. Since the fluoridation of water is extensively practiced in the US, fluoride is not added to salt. Observational studies have shown that the incidence of teeth with caries dramatically decreased in the regions where salt fluoridation programs were developed (reviewed in 72). While concerns around hypertension and the monitoring of population intakes should be addressed, no adverse health effects linked to the fluoridation of salt have been reported (reviewed in 73). According to the World Health Organization (WHO), salt fluoridation and, to a lesser extent, milk fluoridation, are affordable alternatives to improve oral hygiene in areas where access to oral health services is limited and fluoridation of public water is not feasible (74).

Mouth rinses

Mouth rinses that contain fluoride are available over-the-counter in the US. Such products often contain 0.05% sodium fluoride, which translates to about 1 mg of fluoride per 5 mL (one teaspoon) (70). Due to the risk of accidental ingestion, fluoride-containing mouth rinses are not recommended for young children (70).

Professionally applied fluoride products

Professionally applied fluoride products, including fluoride foams, gels, varnish, and silver diamine fluoride, are highly concentrated (9,000 to 44,800 ppm of fluoride) and applied topically to the teeth by dentists, dental hygienists, or other healthcare professionals (75). Because of their high concentrations, they are potential sources of fluoride; however, due to their infrequent use (every 3-6 months) and small amounts used per application, professionally applied fluoride products are not significant sources of fluoride when used as directed (75).

Safety

Adverse effects

Fluoridation of public drinking water in the US was initiated more than 70 years ago. Since then, a number of adverse effects have been attributed to water fluoridation. However, extensive scientific research has uncovered no evidence of increased risks of cancer, heart disease, kidney disease, liver disease, thyroid disease, Alzheimer's disease, birth defects, or Down's syndrome (51, 76, 77).

A number of observational studies, mostly published in Chinese journals, have investigated the association between fluoride content in drinking water and children's neurodevelopment. Two meta-analyses of observational studies, mainly conducted in China, found lower intelligence quotients (IQs) in children exposed to higher fluoride concentrations in drinking water (78, 79). Serious limitations, including substantial heterogeneity among studies and co-occurrence of neurotoxicants in drinking water, hinder the strength of these findings and their application to US settings. The Academy of Nutrition and Dietetics has estimated that only limited evidence supports an association between fluoride content in water and the IQs of children (58). A prospective study in a New Zealand population-based cohort followed for nearly four decades found no association between fluoride exposure in the context of community water fluoridation programs and IQs measured during childhood and at age 38 years (80). A series of recent studies by a research group in Canada have raised concern over a possible link between higher maternal fluoride exposures during pregnancy and lower IQ (81-83), cognitive delay (84), and attention-deficit/hyperactivity disorder (85) in offspring. However, these studies have been widely criticized for shortcomings in measuring fluoride intake, only reporting significant relationships among subgroups, and being observational and subject to residual confounding. Thus, high-quality prospective studies with more definitive fluoride intake measures and better control of confounders are needed to determine whether fluoride might have neurotoxic effects at usual intake levels.

Acute toxicity

Fluoride is toxic when consumed in excessive amounts, so concentrated fluoride products should be used and stored with caution to prevent the possibility of acute fluoride poisoning, especially in children and other vulnerable individuals. The lowest dose that could trigger adverse symptoms is considered to be 5 mg/kg of body weight, with the lowest potentially fatal dose considered 15 mg/kg of body weight. Nausea, abdominal pain, and vomiting almost always accompany acute fluoride toxicity. Other symptoms like diarrhea, excessive salivation and tearing, sweating, and generalized weakness may also occur (77). In order to prevent acute fluoride poisoning, the American Dental Association has recommended that no more than 120 mg of fluoride (224 mg of sodium fluoride) be dispensed at one time (48). The use of high doses of fluoride to treat osteoporosis has been associated with some adverse effects, which are discussed in the Disease Treatment section above.

Dental fluorosis

Dental fluorosis, also called enamel fluorosis, is a result of excess fluoride intake during the period of tooth formation, with the critical window of susceptibility being the first eight years of life, as this corresponds to the eruption of the permanent teeth (86). Once the tooth enamel has formed, dental fluorosis cannot develop (87). The mildest form of dental fluorosis is detectable only to the trained observer and is characterized by small opaque white flecks or spots on the enamel of the teeth. Moderate dental fluorosis is characterized by mottling and mild staining of the teeth, and severe dental fluorosis results in marked staining and pitting of the teeth. In its moderate to severe forms, dental fluorosis becomes a cosmetic concern when it affects the incisors and canines (front teeth). Dental fluorosis is a dose-dependent condition, with higher fluoride intakes being associated with more pronounced effects on the teeth.

The incidence of mild and moderate dental fluorosis has increased over the past decades, mainly due to increasing fluoride intake from reconstituted infant formula and toothpaste, although inappropriate use of fluoride supplements may also contribute (61). According to a US national survey, the National Health and Nutrition Examination Survey (NHANES) 1999-2004, 23% of people aged 6 to 49 years (n=16,051) had some degree of dental fluorosis (88). National data from NHANES 2011-2012 found that the prevalence of fluorosis among children and adolescents (n=2,283), ages 6 to 19 years, was much higher at 57% (89); however, a quality assessment of these data raised concerns about their validity and suggested such results were not biologically plausible (90). In 1997, the US Food and Nutrition Board (FNB) of the Institute of Medicine set the tolerable upper intake level (UL) for fluoride based on the prevention of moderate enamel fluorosis (**Table 4**) (6).

Table 4. Tolerable Upper Intake Level (UL) for Fluoride

Age Group	UL (mg/day)
Infants 0-6 months	0.7
Infants 7-12 months	0.9
Children 1-3 years	1.3
Children 4-8 years	2.2
Children 9-13 years	10.0
Adolescents 14-18 years	10.0
Adults 19 years and older	10.0

The current US EPA maximum allowable level of fluoride in drinking water is 4 mg/L; the EPA also has a non-enforceable standard fluoride level of 2 mg/L to prevent moderate dental fluorosis (91). The EPA recently conducted a six-year review of drinking water standards and concluded that the limit of fluoride in drinking water is not a candidate for regulatory revision at this time (92).

Skeletal fluorosis

Intake of fluoride at excessive levels for long periods of time may lead to changes in bone structure known as skeletal fluorosis. The early stages of skeletal fluorosis are characterized by increased bone mass, detectable by x-ray. If very high fluoride intake persists over many years, joint pain and stiffness may result from the skeletal changes. The most severe form of skeletal fluorosis is known as "crippling skeletal fluorosis," which may result in calcification of ligaments, immobility, muscle wasting, and neurological problems related to spinal cord compression. While skeletal fluorosis is endemic in many world regions with naturally high fluoride concentrations in drinking water, crippling skeletal fluorosis may occur only when fluoride intake exceeds 10 mg/day for at least 10 years (6, 93). Rare cases of skeletal fluorosis in the US have been observed in consumers of large volumes of tea (94-97). Because of the potential risk for skeletal fluorosis, as well as the risks for pitting of tooth enamel and bone fracture, the US EPA set the maximum level of fluoride allowed in drinking water at 4 mg/L (98). The agency also recommended limiting fluoride in drinking water at 2 mg/L to prevent dental fluorosis in children; however, this is only a guideline and not enforceable by law (see the US EPA website).

Drug interactions

Calcium supplements, as well as calcium and aluminum-containing antacids, can decrease the absorption of fluoride. It is best to take these products two hours before or after fluoride supplements (99).

Linus Pauling Institute Recommendation

The safety and public health benefits of optimally fluoridated water for prevention of tooth decay in people of all ages have been well established. The Linus Pauling Institute supports the recommendations of the American Dental Association and the Centers for Disease Control and Prevention, which include optimally fluoridated water and the use of fluoride toothpaste, fluoride mouth rinse, fluoride varnish, and when necessary, fluoride supplementation. Due to the risk of fluorosis, any fluoride supplementation should be prescribed and closely monitored by a dentist or physician.

Summary

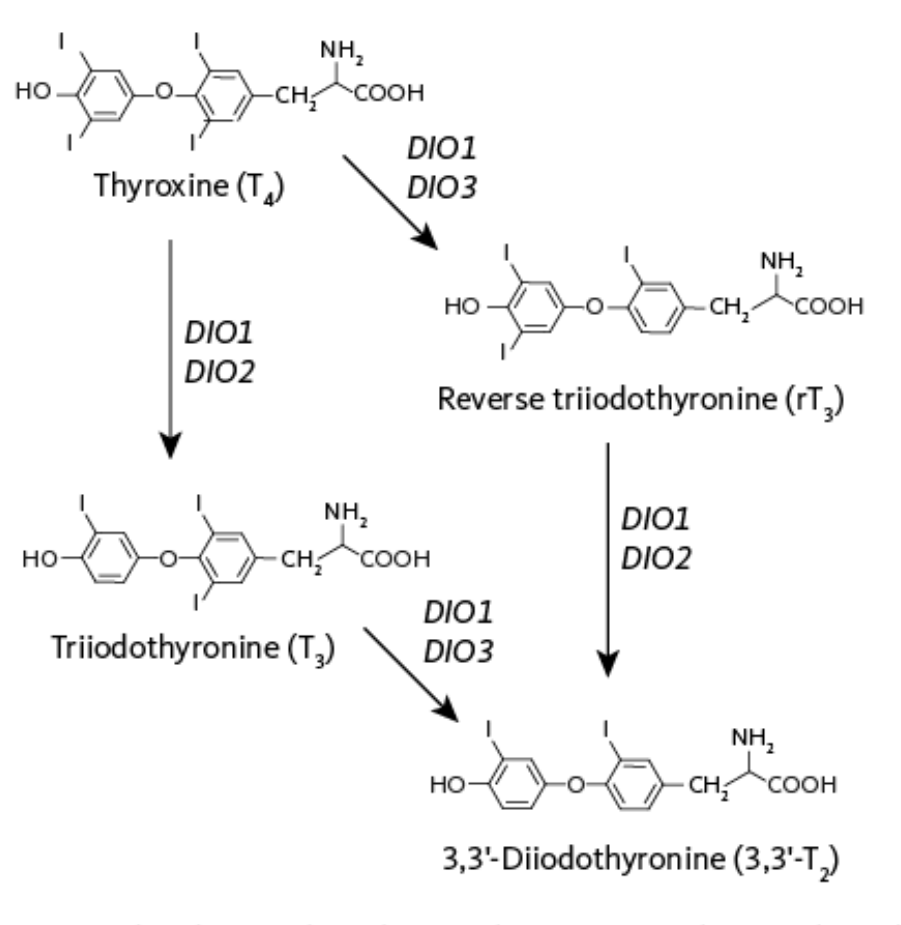
- Iodine is a key component of thyroid hormones, which are required throughout life for normal growth, neurological development, and metabolism. *(More information)*
- Insufficient iodine intake impairs the production of thyroid hormones, leading to a condition called hypothyroidism. Iodine deficiency results in a range of adverse health disorders with varying degrees of severity, from thyroid gland enlargement (goiter) to severe physical and mental retardation known as cretinism. *(More information)*
- Iodine deficiency-induced hypothyroidism has adverse effects in all stages of development but is most damaging to the developing brain. Maternal iodine deficiency during pregnancy can result in maternal and fetal hypothyroidism, as well as miscarriage, preterm birth, and neurological impairments in offspring. *(More information)*
- Even in areas with voluntary/mandatory iodization programs and in iodine-replete countries, pregnant women, lactating mothers, and young infants are among the most vulnerable to iodine deficiency due to their special requirements during these life stages. *(More information)*
- The recommended dietary allowance (RDA) for iodine intake is 150 micrograms (μg)/day in adults, 220 μg/day in pregnant women, and 290 μg/day in breast-feeding women. During pregnancy and lactation, the fetus and infant are entirely reliant on maternal iodine intake for thyroid hormone synthesis. *(More information)*
- Thyroid accumulation of radioactive iodine (^{131}I) increases the risk of developing thyroid cancer, especially in children. In case of radiation emergencies, current preventive measures include the distribution of pharmacologic doses of potassium iodide that would reduce the risk of significant uptake of ^{131}I by the thyroid gland. *(More information)*
- Seafood is an excellent source of dietary iodine. Dairy products, grains, eggs, and poultry contribute substantially to dietary iodine intakes in the US. *(More information)*
- More than 120 countries worldwide have introduced programs of salt fortification with iodine in order to correct iodine deficiency in populations. *(More information)*
- In iodine-deficient populations, a rapid increase in iodine intake may precipitate iodine-induced hyperthyroidism. The risk of iodine-induced hyperthyroidism is especially high in older people with multi-nodular goiter. *(More information)*
- In iodine-sufficient adults, long-term iodine intake above the tolerable upper intake level (UL) of 1,100 μg/day may increase the risk of thyroid disorders, including iodine-induced goiter and hypothyroidism. *(More information)*

Iodine (I), a non-metallic trace element, is required by humans for the synthesis of thyroid hormones. Iodine deficiency is an important health problem throughout much of the world. Most of the Earth's iodine, in the form of the iodide ion (I^-), is found in oceans, and iodine content in the soil varies with region. The older an exposed soil surface, the more likely the iodine has been leached away by erosion. Mountainous regions, such as the Himalayas, Atlas, Andes, and Alps; flooded river valleys, such as the Ganges River plain in India; and many inland regions, such as central Asia and Africa, central and eastern Europe, and the Midwestern region of North America are among the most severely iodine-deficient areas in the world (1).

Function

Iodine is an essential component of the thyroid hormones, triiodothyronine (T_3) and thyroxine (T_4), and is therefore essential for normal thyroid function. To meet the body's demand for thyroid hormones, the thyroid gland traps iodine from the blood and incorporates it into the large (660 kDa) glycoprotein thyroglobulin. The hydrolysis of thyroglobulin by lysosomal enzymes gives rise to thyroid hormones that are stored and released into the circulation when needed. In target tissues, such as the liver and the brain, T_4 (the most abundant circulating thyroid hormone) can be converted to T_3 by selenium-containing enzymes known as iodothyronine deiodinases (DIOs) (**Figure 1**; see also Nutrient interactions). T_3 is the physiologically active thyroid hormone that can bind to thyroid receptors in the nuclei of cells and regulate gene expression. In this manner, thyroid hormones regulate a number of physiologic processes, including growth, development, metabolism, and reproductive function (2).

Figure 1. Deiodination of Thyroid Hormones

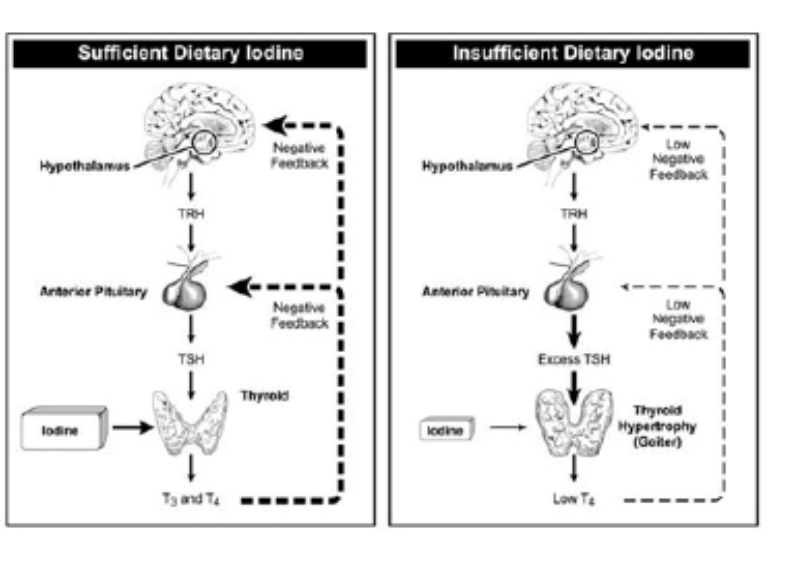


Iodothyronine deiodinases (DIOs) are selenoenzymes that catalyze the deiodination (removal of iodine) from iodothyronines. Specifically, DIO1 and DIO2 catalyze the deiodination of thyroxine (T_4) that generates the biologically active triiodothyronine (T_3). DIO3 inactivates T_3 and T_4 by removing iodine atoms from the inner ring.

[Figure 1 - Click to Enlarge]

The regulation of thyroid function is a complex process that involves the hypothalamus and the pituitary gland. In response to thyrotropin-releasing hormone (TRH) secretion by the hypothalamus, the pituitary gland secretes thyroid-stimulating hormone (TSH), which stimulates iodine trapping, thyroid hormone synthesis, and release of T_4 and T_3 by the thyroid gland. The presence of adequate circulating T_4 and T_3 feeds back at the level of both the hypothalamus and pituitary, decreasing TRH and TSH production (**Figure 2**). When circulating T_4 levels decrease, the pituitary gland increases its secretion of TSH, resulting in increased iodine trapping, as well as increased production and release of both T_3 and T_4. Iodine deficiency results in inadequate production of T_4. In response to decreased blood T_4 concentrations, the pituitary gland increases its output of TSH. Persistently elevated TSH levels may lead to hypertrophy (enlargement) of the thyroid gland, also known as goiter (see Deficiency) (3).

Figure 2. The Hypothalamic-Pituitary-Thyroid Axis



In response to thyrotropin-releasing hormone (TRH) secretion by the hypothalamus, the pituitary gland secretes thyroid-stimulating hormone (TSH). TSH stimulates iodine trapping and thyroid hormone synthesis by the thyroid gland and the release of T_3 (triiodothyronine) and T_4 (thyroxine) into the circulation.

When dietary iodine intake is sufficient, the presence of adequate serum T_4 and T_3 concentrations feeds back at the level of both the hypothalamus and pituitary gland, decreasing TRH and TSH production.

When circulating T_4 concentrations decrease, the pituitary gland increases its secretion of TSH, stimulating iodine trapping and production and release of both T_3 and T_4. In the case of iodine deficiency, persistently elevated TSH levels may lead to hypertrophy of the thyroid gland, also known as goiter.

[Figure 2 - Click to Enlarge]

Deficiency

The thyroid gland of a healthy adult concentrates 70-80% of a total body iodine content of 15-20 mg and utilizes about 80 μg of iodine daily to synthesize thyroid hormones. In contrast, chronic iodine deficiency can result in a dramatic reduction of the iodine content in the thyroid well below 1 mg (1). Iodine deficiency is recognized as the most common cause of preventable brain damage in the world. The spectrum of iodine deficiency disorders (IDD) includes mental retardation, hypothyroidism, goiter, and varying degrees of other growth and developmental abnormalities (4). The World Health Organization (WHO) estimated that over 30% of the world's population (2 billion people) have insufficient iodine intake as measured by median urinary iodine concentrations below 100 μg/L (5). Moreover, about one-third of school-age children (6-12 years old) worldwide (241 million children in 2011) have insufficient iodine intake (6, 7). Major international efforts have produced dramatic improvements in the correction of iodine deficiency in the 1990s, mainly through the use of iodized salt in iodine-deficient countries (4). Although about 70% of households in the world now have access to iodized salt (8), mild-to-moderate iodine deficiency remains a public health concern in at least 30 countries; there are no iodine excretion data available for 42 other countries, including Israel, Syria, and Sierra Leone (7). For more information on the international effort to eradicate iodine deficiency, visit the websites of the Iodine Global Network (formerly the International Council for the Control of Iodine Deficiency Disorders) and the WHO.

Biomarkers of iodine status

More than 90% of ingested iodine is excreted in the urine within 24-48 hours such that daily iodine intakes in a population can be extrapolated from measures of median spot urinary iodine concentrations (9, 10). According to WHO criteria, population iodine deficiency is defined by median urinary iodine concentrations lower than 150 micrograms (μg)/L for pregnant women and 100 μg/L for all other groups (**Table 1**). Adequate intakes correspond to median urinary iodine concentrations of 100-199 μg/L in school-age children and 150-249 μg/L in pregnant women (**Table 1**). While median urinary iodine concentration is a population indicator of recent dietary iodine intake, multiple collections of 24-hour urinary iodine are preferable to estimate intake in individuals (9-11).

Table 1. WHO Criteria for Assessment of Iodine Nutrition through Population-based Median Urinary Iodine Concentrations (4)

Population Group	Median/Range of Urinary Iodine Concentrations (μg/L)	Iodine Intake
Children (<2 years)	<100	Insufficient
	≥100	Adequate
Children (≥6 years), adolescents, and adults*	<100	Insufficient
	100-199	Adequate
	200-299	More than adequate
	>300	Excessive
Pregnant women	<150	Insufficient
	150-249	Adequate
	250-499	More than adequate
	≥500	Excessive
Breast-feeding women#	<100	Insufficient
	≥100	Adequate

*Excludes pregnant or lactating women.
#Given that iodine requirements are increased in breast-feeding women (see The RDA), the numbers for median urinary excretion concentrations are lower than one would expect because iodine is also excreted in breast milk.

In many countries, serum TSH concentration is used in the screening for congenital hypothyroidism in newborns. Newborn TSH can be used as an indicator of population iodine status. Yet, in older children and adults, serum TSH is not a sensitive indicator of iodine status as concentrations are usually maintained within a normal range despite frank iodine deficiency (12). Serum thyroglobulin concentration in school-age children is a sensitive marker of iodine status in populations (13). In areas of endemic goiter, changes in thyroid size reflect long-term iodine nutrition (months to years). Assessment of the goiter rate in a population is used to define the severity of iodine deficiency, as well as to monitor the long-term impact of sustained salt iodization programs (4, 10). Finally, serum thyroid hormone concentrations do not adequately reflect iodine nutrition in populations (1).

Iodine deficiency disorders

All the adverse effects of iodine deficiency in animals and humans are collectively termed iodine deficiency disorders (reviewed in 1). Thyroid enlargement, or goiter, is one of the earliest and most visible signs of iodine deficiency. It is a physiologic adaptation of the thyroid gland in response to persistent stimulation by TSH (see Function). In mild iodine deficiency, thyroid enlargement may be enough to maximize the uptake of available iodine and provide the body with sufficient thyroid hormones. Yet, large goiters can obstruct the trachea and esophagus and damage the recurrent laryngeal nerves.

More severe cases of iodine deficiency result in impaired thyroid hormone synthesis known as hypothyroidism. Adequate iodine intake will generally reduce the size of goiters, but the reversibility of the effects of hypothyroidism depends on an individual's life stage. Iodine deficiency-induced hypothyroidism has adverse effects in all stages of development but is most damaging to the developing brain. In addition to regulating many aspects of growth and development, thyroid hormones are important for the migration, proliferation, and differentiation of specific neuronal populations, the overall architecture of the brain's cortex, the formation of axonal connections, and the myelination of the central nervous system, which occurs both before and shortly after birth (reviewed in 14).

The effects of iodine deficiency at different life stages are discussed below.

Pregnancy and lactation

Daily iodine requirements are significantly increased in pregnant and breast-feeding women because of (1) the increased thyroid hormone production and transfer to the fetus in early pregnancy before the fetal thyroid gland becomes functional, (2) iodine transfer to the fetus during late gestation, (3) increased urinary iodine excretion, and (4) iodine transfer to the infant via breast milk (see also The RDA) (12, 15).

During pregnancy, the size of the thyroid gland is increased by 10% in women residing in iodine-sufficient regions and increased by 20%-40% in those living in iodine-deficient regions (16). Iodine deficiency during pregnancy can result in hypothyroidism in women. Maternal hypothyroidism has been associated with increased risk for preeclampsia, miscarriage, stillbirth, preterm birth, and low-birth-weight infants (reviewed in 16). In addition, severe iodine deficiency during pregnancy may result in congenital hypothyroidism and neurocognitive deficits in the offspring (see Prenatal development) (12).

Iodine-deficient women who are breast-feeding may not be able to provide sufficient iodine to their infants who are particularly vulnerable to the effects of iodine deficiency (see Newborns and infants) (17). A daily prenatal supplement of 150 μg of iodine, as recommended by the American Thyroid Association (ATA) (16), will help to ensure that US pregnant and breast-feeding women consume sufficient iodine during these critical periods. In iodine-deficient areas where iodized salt is not available, the Iodine Global Network (IGN; formerly the International Council for the Control of Iodine Deficiency Disorders), the World Health Organization (WHO), and UNICEF recommend that lactating women receive a single annual dose of 400 mg of iodine (or 250 μg/day) and exclusively breast-feed for at least six months. When breast-feeding is not possible, direct supplementation of the infant (<2 years old) with a single annual dose of 200 mg of iodine (or 90 μg/day) is advised (4). A randomized and placebo-controlled trial recently demonstrated that maternal supplementation (with a single 400-mg dose of iodine) improved the iodine status of breast-fed infants more efficiently than direct infant supplementation (with a single 100 mg-dose of iodine) for a period of at least six months (18). Yet, supplementation of lactating women failed to increase maternal urinary iodine concentrations above 100 μg/L, suggesting that supplemented mothers remained deficient in iodine (18).

Prenatal development

Fetal iodine deficiency is caused by iodine deficiency in the mother (see Pregnancy and lactation). During pregnancy, before the fetal thyroid gland becomes functional at 16-20 weeks' gestation, maternal thyroxine (T_4) crosses the placenta to promote normal embryonic and fetal development. Hence, maternal iodine deficiency and hypothyroidism can result in adverse pregnancy complications, including fetal loss, placental abruption, preeclampsia, preterm delivery, and congenital hypothyroidism in the offspring (16). The effects of maternal hypothyroidism on the offspring depend on the timing and severity of *in utero* iodine deficiency. A severe form of congenital hypothyroidism may lead to cretinism, a condition associated with irreversible mental retardation. The clinical picture of neurological cretinism in the offspring includes severe mental and physical retardation, deafness, mutism, and motor spasticity.

A myxedematous form of cretinism has been associated with coexisting iodine and selenium deficiency in central Africa (see Nutrient interactions) and is characterized by a less severe degree of mental retardation than in neurological cretinism. Yet, affected individuals exhibit all the features of severe hypothyroidism, including severe growth retardation and delayed sexual maturation (12). Two longitudinal cohort studies (one in the UK and one in Australia) recently observed that even mild-to-moderate iodine deficiency during pregnancy was associated with reduced scores of IQ and various measures of literacy performance in children 8 to 9 years of age (19, 20).

Newborns and infants (up to one year of age)

Infant mortality is higher in areas of severe iodine deficiency than in iodine-replete regions, and several studies have demonstrated an increase in childhood survival upon correction of the iodine deficiency (8, 21, 22). Infancy is a period of rapid brain growth and development. Sufficient thyroid hormone, which depends on adequate iodine intake, is essential for normal brain development. Even in the absence of congenital hypothyroidism, iodine deficiency during infancy may result in abnormal brain development and, consequently, impaired intellectual development (23, 24).

Children and adolescents

Iodine deficiency in children and adolescents is often associated with goiter. The incidence of goiter peaks in adolescence and is more common in girls than boys. School-age children in iodine-deficient areas show poorer school performance, lower IQs, and a higher incidence of learning disabilities than matched groups from iodine-sufficient areas. Three meta-analyses of mainly cross-sectional studies concluded that chronic iodine deficiency was associated with reduced mean IQ scores by 7-13.5 points in participants (primarily children) (25-27). However, these observational studies did not distinguish between iodine deficiency during pregnancy and during childhood, and such observational studies may be confounded by social, economic, and educational factors that influence child development.

Adults

Inadequate iodine intake may also result in goiter and hypothyroidism in adults. Although the effects of hypothyroidism are more subtle in the brains of adults than children, research suggests that hypothyroidism results in poor social and economic achievements due to low educability, apathy, and reduced work productivity (28). Other symptoms of hypothyroidism in adults include fatigue, weight gain, cold intolerance, and constipation.

Finally, because iodine deficiency induces an increase in the iodine trapping capacity of the thyroid, iodine-deficient individuals of all ages are more susceptible to radiation-induced thyroid cancer (see Disease Prevention), as well as to iodine-induced hyperthyroidism after an increase in iodine intakes (see Safety) (2).

Individuals and populations at risk of iodine deficiency

While the risk of iodine deficiency for populations living in iodine-deficient areas without adequate iodine fortification programs is well recognized, concerns have been raised that certain subpopulations in countries considered iodine-sufficient may not consume adequate iodine (7, 29). The greater use of methods assessing iodine status (see Biomarkers of iodine status) has shown that iodine deficiency also occurs in areas where the prevalence of goiter is low, in coastal areas, in highly developed countries, and in regions where iodine deficiency was previously eliminated (4).

The US is currently considered to be iodine-sufficient. Yet, in recent years, dietary intakes of iodine in the US population have decreased. Data from the latest US National Health and Nutrition Examination Survey (NHANES 2009-2010) indicated that the median urinary iodine concentration for the general population was 144 μg/L compared to 164 μg/L reported in previous assessments (NHANES 2005-2006 and 2007-2008) (30, 31). In addition to regional differences across the US, ethnic variations have been found. In all age groups, median urinary iodine concentrations were shown to be lower in African Americans than in Hispanics and Caucasians.

In addition, median urinary iodine concentrations in nonpregnant women of childbearing age and pregnant women indicate that mild iodine deficiency has re-emerged in the US in recent years (31).

Nonpregnant women

Data from US NHANES 2007-2010 indicated that 37.3% of nonpregnant women (ages 15-44 years) had urinary iodine concentrations lower than 100 μg/L, reflecting potentially insufficient iodine intakes (see Biomarkers of iodine status) (31). Only one-fifth of nonpregnant women reported using iodine-containing supplements in an earlier NHANES (2001-2006) (32). Yet, adequate intakes of iodine in women of childbearing age (150 μg/day; see The RDA) are essential for optimum stores of iodine, especially if they are considering pregnancy. Some experts suggested a daily consumption of 250 μg of iodine before conception to ensure adequate thyroid hormone production and iodine supply to the embryo and fetus during pregnancy (see Pregnancy and lactation) (12).

Pregnant women

There are no statistics on the global burden of iodine deficiency in pregnant women, but national and regional data suggest that this group is especially vulnerable. Given the increased iodine requirements during pregnancy, the median urinary iodine concentration should be at least of 150 μg/L (see Biomarkers of iodine status). Pooled data from NHANES 2005-2010 reported that US pregnant women had a median urinary iodine concentration of 129 μg/L, and the lowest median concentration (109 μg/L) was observed during the first trimester of gestation, when the embryo/fetus relies exclusively on maternal thyroid hormones (31).

Breast-feeding women

While data regarding the iodine status of breast-feeding women in the US are limited, dietary intakes that were inadequate during pregnancy are likely to be insufficient in a significant fraction of breast-feeding women (33, 34). A systematic review of the literature recently reported suboptimal dietary iodine intakes in breast-feeding women in some countries with a mandatory fortification program, including Denmark, Australia, and India (35). The American Thyroid Association (ATA) recommends that all North American women who are pregnant or breast-feeding supplement their dietary iodine intake with 150 μg/day of iodine (36).

Breast-fed and weaning infants

The body of a healthy newborn contains only about 300 μg of iodine, which makes newborns extremely vulnerable to iodine deficiency (28), and breast-fed infants are entirely reliant on maternal iodine intakes for thyroid hormone synthesis. Even in areas covered by a salt iodization program, weaning infants are at high risk of iodine deficiency, especially if they are not receiving iodine-containing infant formula (17).

Individuals consuming special diets

Diets that exclude iodized salt, fish, and seaweed have been found to contain very little iodine (9). Individuals consuming branded weight-loss foods may also be at risk of inadequate intakes (37). A small US cross-sectional study in 78 vegetarians and 63 vegans reported median urinary iodine concentrations of 147 μg/L and 78.5 μg/L, respectively, suggesting inadequate iodine intakes among vegans (38). Two cases of goiter and/or hypothyroidism have also been recently reported in children following restrictive diets to control esophageal inflammation (eosinophilic esophagitis) (39) or allergies (40).

Patients requiring parenteral nutrition

Although iodine is usually not added to parenteral nutrition (PN) solutions, topical iodine-containing disinfectants and other adventitious sources provide substantial amounts of iodine to some PN patients such that the occurrence of iodine deficiency is unlikely. Yet, deficiency might occur, especially in preterm infants with limited body stores, if chlorhexidine-based antiseptics replace iodinated antiseptics (28, 41).

Nutrient interactions

Concurrent deficiencies in selenium, iron, or vitamin A may exacerbate the effects of iodine deficiency (reviewed in 42).

Selenium

While iodine is an essential component of thyroid hormones, the selenium-containing iodothyronine deiodinases (DIOs) are enzymes (or selenoenzymes) required for the conversion of T_4 to the biologically active thyroid hormone, T_3 (see the article on Selenium). DIO1 activity may also be involved in regulating iodine homeostasis (43). In addition, glutathione peroxidases are selenoenzymes that protect the thyroid gland from hydrogen peroxide-induced damage during thyroid hormone synthesis (44). A randomized, placebo-controlled study in 151 pregnant women at risk of developing autoimmune thyroid disease found that selenium supplementation (200 μg/day in the form of selenomethionine) at 12 weeks of gestation until 12 months' postpartum reduced the risk of thyroid dysfunction and permanent hypothyroidism (45). However, another trial (the Selenium in Pregnancy Intervention Trial) found no benefit of selenium supplementation (60 μg/day from 12-14 weeks of gestation to delivery) over placebo on circulating autoantibody concentrations in pregnant women mildly deficient in iodine (46).

The epidemiology of coexisting iodine and selenium deficiencies in central Africa has been linked to the prevalence of myxedematous cretinism, a severe form of congenital hypothyroidism accompanied by mental and physical retardation. Selenium deficiency may be only one of several undetermined factors that might exacerbate the detrimental effects of iodine deficiency (42). Besides, results from randomized controlled intervention trials have shown that correcting only the selenium deficiency may have a deleterious effect on thyroid hormone metabolism in school-age children with co-existing selenium and iodine deficiency (47, 48). Finally, selenium deficiency in rodents was found to have little impact on DIO activities as it appears that selenium is being supplied in priority for adequate synthesis of DIOs at the expense of other selenoenzymes (44).

Iron

Severe iron-deficiency anemia can impair thyroid metabolism in the following ways: (1) by altering the TSH response of the pituitary gland; (2) by reducing the activity of thyroid peroxidase that catalyzes the iodination of thyroglobulin for the production of thyroid hormones; and (3) in the liver by limiting the conversion of T_4 to T_3, increasing T_3 turnover, and decreasing T_3 binding to nuclear receptors (49). It is estimated that goiter and iron-deficiency anemia coexist in up to 25% of school-age children in west and north Africa (42). A randomized controlled study in iron-deficient children with goiter showed a greater reduction in thyroid size following the consumption of iodized salt together with 60 mg/day of iron four times per week compared to placebo (50). Additional interventions have confirmed that correcting iron-deficiency anemia improved the efficacy of iodine supplementation to mitigate thyroid disorders (reviewed in 42, 49).

Vitamin A

In north and west Africa, vitamin A deficiency and iodine deficiency-induced goiter may coexist in up to 50% of children. Vitamin A status, like other nutritional factors, appears to influence the response to iodine prophylaxis in iodine-deficient populations (51). Vitamin A deficiency in animal models was found to interfere with the pituitary-thyroid axis by (1) increasing the synthesis and secretion of thyroid-stimulating hormone (TSH) by the pituitary gland, (2) increasing the size of the thyroid gland, (3) reducing iodine uptake by the thyroid gland and impairing the synthesis and iodination of thyroglobulin, and (4) increasing circulating concentrations of thyroid hormones (reviewed in 52). A cross-sectional study of 138 children with concurrent vitamin A and iodine deficiencies found that the severity of vitamin A deficiency was associated with higher risk of goiter and higher concentrations of circulating TSH and thyroid hormones (51). These children received iodine-enriched salt together with vitamin A (200,000 IU at baseline and at 5 months) or a placebo in a randomized, double-blind, 10-month trial. Vitamin A supplementation significantly decreased TSH concentration and thyroid volume compared to placebo (51). In another trial, vitamin A supplementation alone (without iodine) to iodine-deficient children reduced the volume of the thyroid gland, as well as TSH and thyroglobulin concentrations (53). Yet, supplemental vitamin A had no additional effect on thyroid function/hormone metabolism when children were also given iodized oil.

Goitrogens

Some foods contain substances that interfere with iodine utilization or thyroid hormone production; these substances are called goitrogens. The occurrence of goiter in the Democratic Republic of Congo has been related to the consumption of cassava, which contains linamarin, a compound that is metabolized to thiocyanate and blocks thyroidal uptake of iodine (1). In iodine-deficient populations, tobacco smoking has been associated with an increased risk for goiter (54, 55). Cyanide in tobacco smoke is converted to thiocyanate in the liver, placing smokers with low iodine intake at risk of developing a goiter. Moreover, thiocyanate affects iodine transport into the lactating mammary gland, leading to low iodine concentrations in breast milk and impaired iodine supply to the neonates/infants of smoking mothers (2). Some species of millet, sweet potatoes, beans, and cruciferous vegetables (e.g., cabbage, broccoli, cauliflower, and Brussels sprouts) also contain goitrogens (1). Further, the soybean isoflavones, genistein and daidzein, have been found to inhibit thyroid hormone synthesis (56). Most of these goitrogens are not of clinical importance unless they are consumed in large amounts or there is coexisting iodine deficiency. Industrial pollutants, such as perchlorate (see Safety), resorcinol, and phthalic acid, may also be goitrogenic (1, 57).

The Recommended Dietary Allowance (RDA)

The RDA for iodine was reevaluated by the Food and Nutrition Board (FNB) of the Institute of Medicine (IOM) in 2001 (**Table 2**). The recommended amounts were calculated using several methods, including the measurement of iodine uptake in the thyroid glands of individuals with normal thyroid function (9). Similar recommendations have been made by several organizations, including the American Thyroid Association (ATA) (16, 58), the World Health Organization (WHO), the Iodine Global Network (IGN; formerly the International Council for the Control of Iodine Deficiency Disorders), and the United Nations Children's Fund (UNICEF) (4). Of note, the WHO, IGN, and UNICEF recommend daily intakes of 250 μg of iodine for both pregnant and breast-feeding women (4).

Table 2. Recommended Dietary Allowance (RDA) for Iodine

Life Stage	Age	Males (μg/day)	Females (μg/day)
Infants	0-6 months	110 (AI)	110 (AI)
Infants	7-12 months	130 (AI)	130 (AI)
Children	1-3 years	90	90
Children	4-8 years	90	90
Children	9-13 years	120	120
Adolescents	14-18 years	150	150
Adults	19 years and older	150	150
Pregnancy	all ages	-	220
Breast-feeding	all ages	-	290

Disease Prevention

Radiation-induced thyroid cancer

Radioactive iodine, especially iodine 131 (^{131}I), may be released into the environment as a result of nuclear reactor accidents, such as the 1986 Chernobyl nuclear accident in Ukraine and the 2011 Fukushima Daiichi nuclear accident in Japan. Thyroid accumulation of radioactive iodine increases the risk of developing thyroid cancer, especially in children (59). The increased iodine trapping activity of the thyroid gland in iodine deficiency results in increased thyroid accumulation of radioactive iodine (^{131}I). Thus, iodine-deficient individuals are at increased risk of developing radiation-induced thyroid cancer because they will accumulate greater amounts of radioactive iodine. Potassium iodide administered in pharmacologic doses (up to 130 mg for adults) within 48 hours before or eight hours after radiation exposure from a nuclear reactor accident can significantly reduce thyroid uptake of ^{131}I and decrease the risk of radiation-induced thyroid cancer (60). The prompt and widespread use of potassium iodide prophylaxis in Poland after the 1986 Chernobyl nuclear reactor accident may explain the lack of a significant increase in childhood thyroid cancer compared to fallout areas where potassium iodide prophylaxis was not widely used (61). In the US, the Nuclear Regulatory Commission (NRC) requires that consideration be given to potassium iodide as a protective measure for the general public in the case of a major release of radioactivity from a nuclear power plant (62). See also the US FDA's Potassium Iodide Information.

Disease Treatment

Fibrocystic breast changes

Fibrocystic breast changes constitute a benign (non-cancerous) condition of the breasts, characterized by lumpiness and discomfort in one or both breasts. Cyst formation and fibrous changes in the appearance of breast tissue occur in at least 50% of premenopausal women and are not usually associated with an increased risk of breast cancer (63). The cause of fibrocystic changes is not known, but variations in hormonal stimulation during menstrual cycles may trigger changes in breast tissue (63).

A few observational studies also suggested an association between benign breast diseases (including but not limited to fibrocystic changes) and thyroid disorders. Recently, a small case-control study (166 cases vs. 72 controls) showed that the frequency of benign breast diseases was greater in women with nodular goiter (54.9%) or Hashimoto thyroiditis (47.4%) than in euthyroid controls (29.2%) (64). Conversely, the prevalence of anti-thyroid autoimmunity and hypothyroidism was found to be significantly higher in women with benign breast diseases compared to controls (65, 66). Interestingly, correcting hypothyroidism with supplemental T_4 was found to improve some of the benign breast disease symptoms, including breast pain (mastalgia) and nipple discharge (65).

In estrogen-treated rats, iodine deficiency leads to changes similar to those seen in fibrocystic breasts, while iodine repletion reverses those changes (67). An uncontrolled study of 233 women with fibrocystic changes found that treatment with aqueous molecular iodine (I_2) at a dose of 0.08 mg of I_2/kg of body weight daily over 6 to 18 months was associated with improvement in pain and other symptoms in over 70% of participants (68). About 10% of the study participants reported side effects that were described by the investigators as minor. A double-blind, placebo-controlled trial of aqueous molecular iodine (0.07-0.09 mg of I_2/kg of body weight daily for six months) in 56 women with fibrocystic changes found that 65% of the women taking molecular iodine reported improvement compared to 33% of those taking the placebo (68). A double-blind, placebo-controlled trial in 87 women with documented breast pain reported that molecular iodine (1.5, 3, or 6 mg/day) for six months improved overall pain (69). In this study, 38.5% of the women receiving 1.5 mg/day, 37.9% of those receiving 3 mg/day, and 51.7% of those receiving 6 mg/day reported at least a 50% reduction in self-assessed breast pain compared to 8.3% in the placebo group.

Large-scale, controlled clinical trials are needed to determine the therapeutic value of molecular iodine in fibrocystic breasts. Besides, the doses of iodine used in these studies (1.5 to 6 mg/day for a 60 kg person) are higher than the tolerable upper intake level (UL) recommended by the Food and Nutrition Board of the Institute of Medicine and should only be used under medical supervision (see Safety).

Sources

Food sources

Data from the ongoing US Total Diet Study, which monitors the levels of some contaminants and nutrients in food products, indicates that dietary iodine intakes in adults range between 138 and 268 micrograms (μg)/day. Considerably higher average intakes (304-353 μg/day of iodine) were reported for boys 14 to 16 years of age (70).

Seafood is rich in iodine because marine animals can concentrate the iodine from seawater. Certain types of edible seaweed (e.g., wakame) are also very rich in iodine (71). The iodine content of food that is grown or raised on a particular soil depends on the iodine content of this soil. In the US, dairy products contribute up to 90% of total estimated iodine intakes in infants, at least 70% in children (ages, 2-10 years), 53%-63% in adolescents (ages, 14-16 years), and about 50% in adults (70). In the UK and northern Europe, iodine levels in dairy products tend to be lower in summer when cattle are allowed to graze in pastures with low soil iodine content (9).

Other good sources of dietary iodine include eggs, fruit, grain products, and poultry (70). Processed foods can contribute to iodine intake if iodized salt or food additives, such as calcium iodate and potassium iodate, are added during production. Yet, in the US, virtually no iodized salt is used in the manufacturing of processed food and fast food products, and the food industry is not required to list the iodine content on food packaging (72). **Table 3** lists the iodine content of some iodine-rich foods in micrograms (μg). Because the iodine content of foods can vary considerably, these values should be considered approximate (73).

Table 3. Some Food Sources of Iodine

Food	Serving	Iodine (μg)
Salt (iodized)	1 gram	77
Cod	3 ounces*	99
Shrimp	3 ounces	35
Fish sticks	2 fish sticks	35
Tuna, canned in oil	3 ounces (½ can)	17
Milk (cow's)	1 cup (8 fluid ounces)	99
Egg, boiled	1 large	12
Navy beans, cooked	½ cup	32
Potato with peel, baked	1 medium	60
Turkey breast, baked	3 ounces	34
Seaweed	¼ ounce, dried	Variable; may be greater than 4,500 μg (4.5 mg)

*A three-ounce serving of meat is about the size of a deck of cards.

Supplements

Over-the-counter iodine supplements

Potassium iodide is available as a nutritional supplement, typically in combination products, such as multivitamin/mineral supplements. Iodine makes up approximately 77% of the total weight of potassium iodide (56). A multivitamin/mineral supplement that contains 100% of the daily value (DV) for iodine provides 150 μg of iodine. Although most people in the US consume sufficient iodine in their diets (see Sources), an additional 150 μg/day is unlikely to result in excessive iodine intake. The American Thyroid Association (ATA) recommends prenatal supplementation with 150 μg/day of iodine and advises against the ingestion of ≥500 μg/day of iodine from iodine, potassium iodine, and kelp supplements for children and adults, and during pregnancy and lactation (see also Safety) (36, 74).

Iodine fortification programs

The fortification of salt with iodine is a feasible and inexpensive method to eliminate iodine deficiency, and salt iodization programs have been implemented in almost all countries. In North America, salt fortification with iodine is mandated in Canada and some parts of Mexico, but only voluntary in the US such that only 52% of US table salt is iodized and only one-fifth of the total salt consumed in the US is iodized (72, 75). Potassium iodide (KI), cuprous iodide (CuI), and potassium iodate (KIO_3) are used to iodize salt. The US Food and Drug Administration (FDA) recommends between 46 and 76 μg of iodine per gram of salt in iodized salt. However, the recent analysis of 88 US iodized food-grade salt samples revealed that the iodine content was below the recommended range in 52% of the samples and above the range in 7% of the samples (76).

In other countries, salt commonly contains 20-50 μg of iodine per gram of salt, depending on local regulations (76). In countries like Denmark (77), Australia (78, 79), and New Zealand (80), the use of iodized salt in the bread-making process is mandated. Additional approaches have been explored, including sugar fortification (81), egg fortification (82), use of iodized salt in the preparation of fermented fish and fish sauce (83), and use of iodine-rich crop fertilizers (84). In addition, fortification of livestock feeds with iodine and the use of iodophors for sanitation during milking contribute to increasing iodine content in dairy products (85). Finally, annual doses of iodized vegetable oil are administered orally or intramuscularly to individuals in iodine-deficient populations who do not have access to iodized salt (4, 56).

Safety

Acute toxicity

Acute iodine poisoning is rare and usually occurs only with doses of many grams. Symptoms of acute iodine poisoning include burning of the mouth, throat, and stomach, fever, nausea, vomiting, diarrhea, a weak pulse, cyanosis, and coma (1).

Excessive iodine intakes

Risk of iodine-induced hyperthyroidism in iodine-deficient individuals

Iodine supplementation programs in iodine-deficient populations have been associated with an increased incidence of iodine-induced hyperthyroidism (IIH), especially in older people with multi-nodular goiter (86). Iodine intakes of 150-200 μg/day have been found to increase the incidence of IIH in iodine-deficient populations. Iodine deficiency increases the risk of developing autonomous thyroid nodules that are unresponsive to TSH control (see Function). These autonomous nodules may then overproduce thyroid hormones in response to sudden iodine supply. IIH symptoms include weight loss, tachycardia (high pulse rate), muscle weakness, and skin warmth. IIH can be dangerous in individuals with underlying heart disease. Yet, because the primary cause of nodular goiter and IIH is chronic iodine deficiency, the benefit of iodization programs largely outweighs the risk of IIH in iodine-deficient populations (1).

Risk of hypothyroidism in iodine-sufficient individuals

In iodine-sufficient individuals, excess iodine intake is most commonly associated with elevated blood concentrations of thyroid stimulating hormone (TSH) that inhibit thyroid hormone production, leading to hypothyroidism and goiter. A slightly elevated serum TSH concentration without a decrease in serum T_4 or T_3 is the earliest sign of abnormal thyroid function when iodine intake is excessive. In iodine-sufficient adults, elevated serum TSH has been found at chronic iodine intakes of ≥750 μg/day in children and ≥1,700 μg/day in adults. Because various edible seaweed species substantially contribute to traditional Asian meals, average Japanese dietary intakes are estimated to range between 1,000 and 3,000 μg of iodine/day (71). Iodine-induced goiter and hypothyroidism are not uncommon in Japan and can be reversed by restricting seaweed intake (71). Prolonged intakes of more than 18,000 μg/day (18 mg/day) increase the incidence of goiter in adults. In newborns, iodine-induced goiter and hypothyroidism can be due to either high maternal intakes or high exposure to iodized antiseptics (87). In order to minimize the risk of adverse health effects, the Food and Nutrition Board of the US Institute of Medicine set a tolerable upper intake level (UL) for iodine that is likely to be safe in almost all individuals. The UL values for iodine are listed in **Table 4** by age group; the UL does not apply to individuals who are being treated with iodine under medical supervision (74).

Table 4. Tolerable Upper Intake Level (UL) for Iodine

Age Group	UL (μg/day)
Infants 0-12 months	Not possible to establish*
Children 1-3 years	200
Children 4-8 years	300
Children 9-13 years	600
Adolescents 14-18 years	900
Adults 19 years and older	1,100

*Source of intake should be from food and formula only.

Individuals with increased sensitivity to excess iodine intake

Individuals with iodine deficiency and those with preexisting thyroid disease, including nodular goiter, autoimmune Hashimoto thyroiditis, Graves disease, and a history of partial thyroidectomy, may be sensitive to iodine intake levels considered safe for the general population and may not be protected by the UL for iodine (9). Infants, the elderly, and pregnant and lactating women may also be more susceptible to excess iodine (see Supplements) (74).

Do elevated and/or insufficient iodine intakes increase the risk of thyroid cancer?

Over the past decades, the incidence of thyroid cancer has increased worldwide. In the US, the incidence of thyroid cancer — representing 4% of all newly diagnosed cancers — has increased from 4.9 cases per persons in 1983 to 14.7 cases per 100,000 persons in 2011, but mortality rate from thyroid cancer has remained low (about 0.5 per 100,000 persons) (88). Accounting for over 80% of all thyroid cancers, thyroid papillary cancer is less aggressive and has a better prognosis than thyroid follicular cancer or anaplastic thyroid cancer. The increasing incidence of thyroid cancer worldwide is likely due at least in part to the improved screening and diagnosis activities. However, because it has coincided with the introduction of iodine fortification programs, a possible contribution of increased iodine intakes has been hypothesized. Yet, in the US, the increasing incidence of thyroid cancers (primarily papillary cancer) over the last few decades was paralleled with a reduction in average iodine intake (89).

Ecologic studies also suggested that iodine prophylaxis in populations that were previously iodine deficient was associated with an increased incidence of the papillary rather than the follicular cancer subtype, and with a reduced incidence of the more aggressive anaplastic thyroid cancer (89). While changes in iodine intakes appear to affect the histological type of thyroid cancer, it is not yet clear whether iodine deficiency and/or iodine excess increase the risk of thyroid cancer (88).

Drug interactions

Amiodarone, a medication used to prevent abnormal heart rhythms, contains high levels of iodine and may affect thyroid function (90, 91). Antithyroid drugs used to treat hyperthyroidism, such as propylthiouracil (PTU), methimazole, and carbimazole, may increase the risk of hypothyroidism. Additionally, the long-term use of lithium to treat mood disorders may increase the risk of hypothyroidism (92). Further, the use of pharmacologic doses of potassium iodide may decrease the anticoagulant effect of warfarin (coumarin) (56).

Contaminants

Perchlorate is an oxidizing agent found in rocket propellants, airbags, fireworks, herbicides, and fertilizer. Mainly as a result of human activity, perchlorate has been found to contaminate drinking water and many foods (57). Chronic exposure to perchlorate concentrations at levels greater than 20 μg per kg body weight (bw) per day interferes with iodine uptake by the thyroid gland and may lead to hypothyroidism (93). The US Environmental Protection Agency (EPA) recommends that daily oral exposure to perchlorate should not exceed 0.7 μg/kg bw to protect the most sensitive population, i.e., the fetuses of pregnant women who might be deficient in iodine and/or hypothyroid (94). Among all age groups, children aged two years have the highest estimated perchlorate intakes per day with 0.35-0.39 μg/kg bw/day. Average estimated intakes of perchlorate in US adults range between 0.08 and 0.11 μg/kg bw/day (70).

Linus Pauling Institute Recommendation

The RDA for iodine is sufficient to ensure normal thyroid function. There is presently no evidence that iodine intakes higher than the RDA are beneficial. Most people in the US consume sufficient iodine in their diets, making supplementation unnecessary.

Pregnant and breast-feeding women

Given the importance of sufficient iodine during prenatal development and infancy, pregnant and breast-feeding women should take a supplement that provides 150 μg of iodine per day (see Deficiency).

Older adults (>50 years)

Because aging has not been associated with significant changes in the requirement for iodine, the LPI recommendation for iodine intake is not different for older adults.

Summary

- Iron is an essential component of hundreds of proteins and enzymes that support essential biological functions, such as oxygen transport, energy production, and DNA synthesis. Hemoglobin, myoglobin, cytochromes, and peroxidases require iron-containing heme as a prosthetic group for their biological activities. *(More information)*
- Because the body excretes very little iron, iron metabolism is tightly regulated. In particular, the iron regulatory hormone, hepcidin, blocks dietary iron absorption, promotes cellular iron sequestration, and reduces iron bioavailability when body iron stores are sufficient to meet requirements. *(More information)*
- Iron status can be assessed in healthy men and nonpregnant women using laboratory tests that measure serum ferritin (iron-storage protein), serum iron, total iron binding capacity, saturation of transferrin (the main iron carrier in blood), and soluble transferrin receptor. *(More information)*
- Iron deficiency results from an inadequate supply of iron to cells following depletion of the body's reserves. Microcytic anemia occurs when body iron stores are so low that hemoglobin synthesis and red blood cell formation are severely impaired. *(More information)*
- Iron deficiency is the most common nutritional deficiency worldwide, affecting primarily children, women of childbearing age, pregnant women, frequent blood donors, and individuals with certain medical conditions. *(More information)*
- Much of our iron requirement is met through recycling iron from senescent red blood cells. The recommended dietary allowance (RDA) for iron is 8 mg/day for men and postmenopausal women, 18 mg/day for premenopausal women, and 27 mg/day for pregnant women. *(More information)*
- Iron deficiency with or without anemia in children has been associated with poor cognitive development, poor school achievement, and abnormal behavior patterns. Limited evidence suggests that iron supplementation has no effect on psychomotor development and cognitive function of anemic iron-deficient infants younger than three years but may improve attention and concentration in older children, adolescents, and women with anemia and/or iron deficiency. *(More information)*
- Heme iron comes from hemoglobin and myoglobin in animal food sources and represents 10%-15% of total dietary iron intake of meat eaters. Yet, because it is much better absorbed than nonheme iron found in both plant and animal food sources, heme iron contributes up to 40% of total absorbed iron. *(More information)*
- Toxic iron deposition in vital organs in patients affected by hereditary hemochromatosis has been associated with numerous chronic conditions, including liver cancer and type 2 diabetes mellitus. Increased heme iron intake and/or loss of iron homeostasis might also increase the risk of chronic disease in individuals free of genetic disorders. *(More information)*
- Iron supplementation may cause gastrointestinal irritation, nausea, vomiting, diarrhea, or constipation, and interfere with the absorption and efficacy of certain medications, including antibiotics and drugs used to treat osteoporosis, hypothyroidism, or Parkinson's disease symptoms. *(More information)*

Iron is the fourth most abundant element of Earth's crust and one of the best studied micronutrients in nutrition science (1, 2). It is a key element in the metabolism of all living organisms. Iron exists in two biologically relevant oxidation states: the ferrous form (Fe^{2+}) and the ferric form (Fe^{3+}). Iron is an essential component of hundreds of proteins and enzymes supporting essential biological functions, such as oxygen transport, energy production, DNA synthesis, and cell growth and replication.

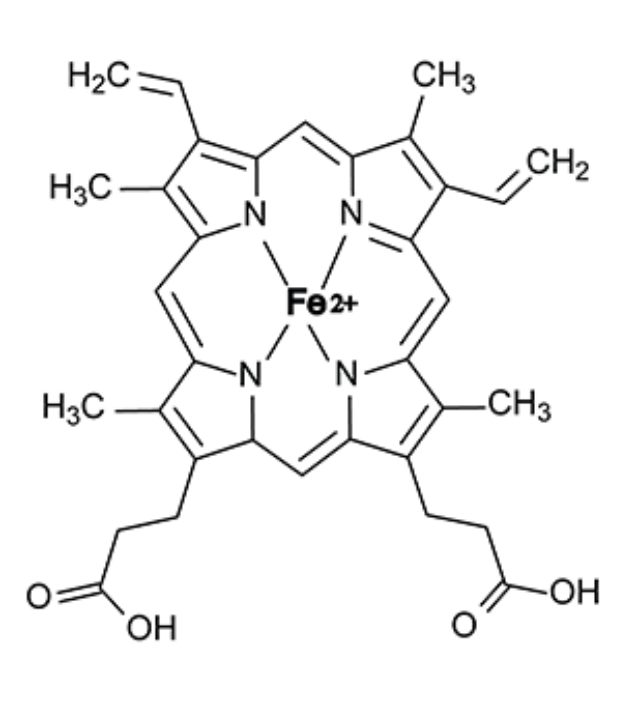
Function

Heme is an iron-containing compound found in a number of biologically important molecules (**Figure 1**). Some, but not all, iron-dependent proteins are heme-containing proteins (also called hemoproteins). Iron-dependent proteins that carry out a broad range of biological activities may be classified as follows (1, 3):

- Globin-heme: nonenzymatic proteins involved in oxygen transport and storage (e.g., hemoglobin, myoglobin, neuroglobin)
- Heme enzymes involved in electron transfer (e.g., cytochromes a, b, f; cytochrome c oxidase) and/or with oxidase activity (e.g., sulfite oxidase, cytochrome P450 oxidases, myeloperoxidase, peroxidases, catalase, endothelial nitric oxide synthase, cyclooxygenase)
- Iron-sulfur (Fe-S) cluster proteins with oxidoreductase activities involved in energy production (e.g., succinate dehydrogenase, isocitrate dehydrogenase, NADH dehydrogenase, aconitase, xanthine oxidase, ferredoxin-1) or involved in DNA replication and repair (DNA polymerases, DNA helicases)
- Nonheme enzymes that require iron as a cofactor for their catalytic activities (e.g., phenylalanine, tyrosine, tryptophan, and lysine hydroxylases; hypoxia-inducible factor (HIF) prolyl and asparaginyl hydroxylases; ribonucleotide reductase)
- Nonheme proteins responsible for iron transport and storage (e.g., ferritin, transferrin, haptoglobin, hemopexin, lactoferrin).

Iron-containing proteins support a number of functions, some of which are listed below.

Figure 1. Structure of Heme b



Oxygen transport and storage

Globin-hemes are heme-containing proteins that are involved in the transport and storage of oxygen and, to a lesser extent, may act as free radical scavengers (1). Hemoglobin is the primary protein found in red blood cells and represents about two-thirds of the body's iron (3). The vital role of hemoglobin in transporting oxygen from the lungs to the rest of the body is derived from its unique ability to acquire oxygen rapidly during the short time it spends in contact with the lungs and to release oxygen as needed during its circulation through the tissues. Myoglobin functions in the transport and short-term storage of oxygen in muscle cells, helping to match the supply of oxygen to the demand of working muscles (1). A third globin called neuroglobin is preferentially expressed in the central nervous system, but its function is not well understood (4).

Electron transport and energy metabolism

Cytochromes are heme-containing enzymes that have important roles in mitochondrial electron transport required for cellular energy production and thus life. Specifically, cytochromes serve as electron carriers during the synthesis of ATP, the primary energy storage compound in cells. Cytochrome P450 (CYP) is a family of enzymes involved in the metabolism of a number of important biological molecules (including organic acids; fatty acids; prostaglandins; steroids; sterols; and vitamins A, D, and K), as well as in the detoxification and metabolism of drugs and pollutants. Nonheme iron-containing enzymes in the citric acid cycle, such as NADH dehydrogenase and succinate dehydrogenase, are also critical to energy metabolism (1).

Antioxidant and beneficial pro-oxidant functions

Catalase and some peroxidases are heme-containing enzymes that protect cells against the accumulation of hydrogen peroxide, a potentially damaging reactive oxygen species (ROS), by catalyzing a reaction that converts hydrogen peroxide to water and oxygen. As part of the immune response, some white blood cells engulf bacteria and expose them to ROS in order to kill them. The synthesis of one such ROS, hypochlorous acid, by neutrophils is catalyzed by the heme-containing enzyme myeloperoxidase (1).

In addition, in the thyroid gland, heme-containing thyroid peroxidase catalyzes the iodination of thyroglobulin for the production of thyroid hormones such that thyroid metabolism can be impaired in iron deficiency and iron-deficiency anemia (see Nutrient Interactions).

Oxygen sensing

Inadequate oxygen (hypoxia), such as that experienced by those who live at high altitudes or those with chronic lung disease, induces compensatory physiologic responses, including increased red blood cell formation (erythropoiesis), increased blood vessel growth (angiogenesis), and increased production of enzymes utilized in anaerobic metabolism. Hypoxia is also observed in pathological conditions like ischemia/stroke and inflammatory disorders. Under hypoxic conditions, transcription factors known as hypoxia-inducible factors (HIF) bind to response elements in genes that encode various proteins involved in compensatory responses to hypoxia and increase their synthesis. Iron-dependent enzymes of the dioxygenase family, HIF prolyl hydroxylases and asparaginyl hydroxylase (factor inhibiting HIF-1 [FIH-1]), have been implicated in HIF regulation. When cellular oxygen tension is adequate, newly synthesized HIF-α subunits (HIF-1α, HIF-2α, HIF-3α) are modified by HIF prolyl hydroxylases in an iron/2-oxoglutarate-dependent process that targets HIF-α for rapid degradation. FIH-1-induced asparaginyl hydroxylation of HIF-α impairs the recruitment of co-activators to HIF-α transcriptional complex and therefore prevents HIF-α transcriptional activity. When cellular oxygen tension drops below a critical threshold, prolyl hydroxylase can no longer target HIF-α for degradation, allowing HIF-α to bind to HIF-1β and form a transcription complex that enters the nucleus and binds to specific hypoxia response elements (HRE) on target genes like the erythropoietin gene (*EPO*) (5).

DNA replication and repair

Ribonucleotide reductases (RNRs) are iron-dependent enzymes that catalyze the synthesis of deoxyribonucleotides required for DNA replication. RNRs also facilitate DNA repair in response to DNA damage. Other enzymes essential for DNA synthesis and repair, such as DNA polymerases and DNA helicases, are Fe-S cluster proteins. Although the underlying mechanisms are still unclear, depletion of intracellular iron was found to inhibit cell cycle progression, growth, and division. Inhibition of heme synthesis also induced cell cycle arrest in breast cancer cells (6).

Iron is required for a number of additional vital functions, including growth, reproduction, healing, and immune function.

Regulation

Systemic regulation of iron homeostasis

While iron is an essential mineral, it is potentially toxic because free iron inside the cell can lead to the generation of free radicals causing oxidative stress and cellular damage. Thus, it is important for the body to systemically regulate iron homeostasis. The body tightly regulates the transport of iron throughout various body compartments, such as developing red blood cells (erythroblasts), circulating macrophages, liver cells (hepatocytes) that store iron, and other tissues (7). Intracellular iron concentrations are regulated according to the body's iron needs (see below), but extracellular signals also regulate iron homeostasis in the body through the action of hepcidin.

Hepcidin, a peptide hormone primarily synthesized by liver cells, is the key regulator of systemic iron homeostasis. Hepcidin can induce the internalization and degradation of the iron-efflux protein, ferroportin-1; ferroportin-1 regulates the release of iron from certain cells, such as enterocytes, hepatocytes, and iron-recycling macrophages, into plasma (8). When body iron concentration is low and in situations of iron-deficiency anemia, hepcidin expression is minimal, allowing for iron absorption from the diet and iron mobilization from body stores. In contrast, when there are sufficient iron stores or in the case of iron overload, hepcidin inhibits dietary iron absorption, promotes cellular iron sequestration, and reduces iron bioavailability. Hepcidin expression is up-regulated in conditions of inflammation and endoplasmic reticulum stress and down-regulated in hypoxia (9). In Type 2B hemochromatosis, deficiency in hepcidin due to mutations in the hepcidin gene, *HAMP*, causes abnormal iron accumulation in tissues (see Iron Overload). Of note, hepcidin is also thought to have a major antimicrobial role in the innate immune response by limiting iron availability to invading microorganisms (see Iron withholding defense during infection) (10).

Regulation of intracellular iron

Iron-responsive elements (IREs) are short sequences of nucleotides found in the messenger RNAs (mRNAs) that code for key proteins in the regulation of iron storage, transport, and utilization. Iron regulatory proteins (IRPs: IRP-1, IRP-2) can bind to IREs and control mRNA stability and translation, thereby regulating the synthesis of specific proteins, such as ferritin (iron storage protein) and transferrin receptor-1 (TfR; controls cellular iron uptake) (1, 2).

When the iron supply is low, iron is not available for storage or release into plasma. Less iron binds to IRPs, allowing the binding of IRPs to IREs. The binding of IRPs to IREs located in the 5'end of mRNAs coding for ferritin and ferroportin-1 (iron efflux protein) inhibits mRNA translation and protein synthesis. Translation of mRNA that codes for the key regulatory enzyme of heme synthesis in immature red blood cells is also reduced to conserve iron. In contrast, IRP binding to IREs in the 3' end of mRNAs that code for TfR and divalent metal transporter-1 (DMT1) stimulates the synthesis of iron transporters, thereby increasing iron uptake into cells (1, 2).

When the iron supply is high, more iron binds to IRPs, thereby preventing the binding of IRPs to IREs on mRNAs. This allows for an increased synthesis of proteins involved in iron storage (ferritin) and efflux (ferroportin-1) and a decreased synthesis of iron transporters (TfR and DMT1) such that iron uptake is limited (2). In the brain, IRPs are also prevented from binding to the 5'end of amyloid precursor protein (APP) mRNA, allowing for APP expression. APP stimulates iron efflux from neurons through stabilizing ferroportin-1. In Parkinson's disease (PD), APP expression is inappropriately suppressed, leading to iron accumulation in dopaminergic neurons (11, 12).

Iron withholding defense during infection

Iron is required by most infectious agents to grow and spread, as well as by the infected host in order to mount an effective immune response. Sufficient iron is critical for the differentiation and proliferation of T lymphocytes and the generation of reactive oxygen species (ROS) required for killing pathogens (13). During infection and inflammation, hepcidin synthesis is up-regulated, serum iron concentrations decrease, and concentrations of ferritin (the iron storage protein) increase, supporting the idea that sequestering iron from pathogens is an important host defense mechanism (2).

Recycling of iron

Total body content of iron in adults is estimated to be 2.3 g in women and 3.8 g in men (2). The body excretes very little iron; basal losses, menstrual blood loss, and the need of iron for the synthesis of new tissue are compensated by the daily absorption of a small proportion of dietary iron (1 to 2 mg/day). Body iron is primarily found in red blood cells, which contain 3.5 mg of iron per g of hemoglobin. Senescent red blood cells are engulfed by macrophages in the spleen, and about 20 mg of iron can be recovered daily from heme recycling. The released iron is either deposited to the ferritin of spleen macrophages or exported by ferroportin-1 (iron efflux protein) to transferrin (the main iron carrier in blood) that delivers iron to other tissues. Iron recycling is very efficient, with about 35 mg being recycled daily (1).

Assessment of iron status

Measurements of iron stores, circulating iron, and hematological parameters may be used to assess the iron status of healthy people in the absence of inflammatory disorders, parasitic infection, and obesity. Commonly used iron status biomarkers include serum ferritin (iron-storage protein), serum iron, total iron binding capacity (TIBC), and saturation of transferrin (the main iron carrier in blood; TSAT). Soluble transferrin receptor (sTfR) is also an indicator of iron status when iron stores are depleted. In iron deficiency and iron-deficiency anemia, the abundance of cell surface-bound transferrin receptors that bind diferric transferrin is increased in order to maximize the uptake of available iron. Therefore, the concentration of sTfR generated by the cleavage of cell-bound transferrin receptors is increased in iron deficiency. Hematological markers, including hemoglobin concentration, mean corpuscular hemoglobin concentration, mean corpuscular volume of red blood cells, and reticulocyte hemoglobin content can help detect abnormality if anemia is present (9, 14).

Of note, serum ferritin is an acute-phase reactant protein that is up-regulated by inflammation. Importantly, serum hepcidin concentration is also increased by inflammation to limit iron availability to pathogens. Therefore, it is important to include inflammation markers (e.g., C-reactive protein, fibrinogen) when assessing iron status to rule out inflammation (14).

Nutrient Interactions

Vitamin A

Vitamin A deficiency often coexists with iron deficiency and may exacerbate iron-deficiency anemia by altering iron metabolism (15). Vitamin A supplementation has been shown to have beneficial effects on iron-deficiency anemia and improve iron nutritional status among children and pregnant women (15, 16). The combination of vitamin A and iron seems to reduce anemia more effectively than either supplemental iron or vitamin A alone (17). Vitamin A may facilitate the mobilization of iron from storage sites to developing red blood cells for incorporation into hemoglobin (15, 16). Moreover, studies in rats have shown that iron deficiency alters plasma and liver levels of vitamin A (18, 19).

Copper

Adequate copper nutritional status is necessary for normal iron metabolism and red blood cell formation. Anemia is a clinical sign of copper deficiency, and iron has been found to accumulate in the livers of copper-deficient animals, indicating that copper (via copper-containing ceruloplasmin) is required for iron transport to the bone marrow for red blood cell formation (20). The connection between copper availability and iron metabolism has also been established in humans; copper deficiency can lead to secondary ceruloplasmin deficiency and hepatic iron overload and/or cirrhosis (21). Oral copper supplementation restored normal ceruloplasmin levels and plasma ferroxidase activity and corrected the iron metabolism disorder in a copper-deficient subject (22). Moreover, infants fed a high-iron formula absorbed less copper than infants fed a low-iron formula, suggesting that high iron intakes may interfere with copper absorption in infants (23).

Zinc

Zinc is essential to maintain adequate erythropoiesis. When zinc deficiency coexists with iron deficiency, it may exacerbate iron-deficiency anemia (24). On the other hand, high doses of iron supplements, taken together with zinc supplements on an empty stomach, may inhibit the absorption of zinc. When taken with food, supplemental iron does not appear to inhibit zinc absorption. Iron-fortified foods have not been found to impair zinc absorption (25, 26).

Calcium

The presence of calcium decreases iron absorption from both nonheme (i.e., most supplements and food sources other than meat, poultry, and seafood) and heme sources (27). However, calcium supplementation up to 12 weeks has not been found to change iron nutritional status, probably due to a compensatory increase in iron absorption (28). Individuals taking iron supplements should take them two hours apart from calcium-rich food or supplements to maximize iron absorption.

Iodine

Severe iron-deficiency anemia can impair thyroid metabolism in the following ways: (1) by altering the thyroid-stimulating hormone response of the pituitary gland; (2) by reducing the activity of thyroid peroxidase that catalyzes the iodination of thyroglobulin for the production of thyroid hormones; and (3) in the liver by limiting the conversion of T_4 to T_3, increasing T_3 turnover, and decreasing T_3 binding to nuclear receptors (29). It is estimated that goiter and iron-deficiency anemia coexist in up to 25% of school-age children in west and north Africa (30). A randomized controlled study in iron-deficient children with goiter showed a greater reduction in thyroid size following the consumption of iodized salt together with 60 mg/day of iron four times per week compared to placebo (31). Additional interventions have confirmed that correcting iron-deficiency anemia improved the efficacy of iodine supplementation to mitigate thyroid disorders (reviewed in 29, 30).

Deficiency

Levels of iron deficiency

Iron deficiency is the most common nutrient deficiency in the US and the world. Levels of iron deficiency are listed below from least to most severe.

Storage iron depletion

Iron stores are depleted, but the functional iron supply is not limited.

Early functional iron deficiency

Before the development of frank anemia, the supply of functional iron to tissues, including bone marrow, is inadequate such as to impair erythropoiesis.

Iron-deficiency anemia

By definition, anemia is present when individual hemoglobin concentrations fall below two standard deviations of the distribution mean for hemoglobin in a healthy population of the same gender and age and living at the same altitude (32). In 2013, iron-deficiency anemia was the leading cause of years lived with disability in children and adolescents in the 50 most populous countries. The countries with the highest prevalence of iron-deficiency anemia in individuals younger than 19 years were Afghanistan (41%) and Yemen (39.8%); India contributed the largest number of cases of anemia (147.9 million). The prevalence in the US was estimated to be 19.3% with nearly 16 million cases of iron-deficiency anemia in children and adolescents (33).

Iron-deficiency anemia occurs when there is inadequate iron to support normal red blood cell formation. The anemia of iron deficiency is usually characterized as microcytic and hypochromic, i.e., red blood cells are measurably smaller than normal and their hemoglobin content is decreased such that they are paler than normal. At this stage of iron deficiency, symptoms may be a result of inadequate oxygen delivery due to anemia and/or suboptimal function of iron-dependent enzymes. Changes in hematological parameters are used in the clinical diagnosis of iron-deficiency anemia (see Assessment of iron status). It is important to remember that iron deficiency is not the only cause of anemia, and that the diagnosis or treatment of iron deficiency solely on the basis of anemia may lead to misdiagnosis or inappropriate treatment of the underlying cause (34). See also the articles on Folate and Vitamin B_{12} for information on other nutritional causes of anemia.

Symptoms of iron deficiency

Most of the symptoms of iron deficiency are a result of the associated anemia and may include fatigue, rapid heart rate, palpitations, and rapid breathing on exertion. Iron deficiency impairs athletic performance and physical work capacity in several ways. In iron-deficiency anemia, the reduced hemoglobin content of red blood cells results in decreased oxygen delivery to active tissues. Decreased myoglobin levels in muscle cells limit the amount of oxygen that can be delivered to mitochondria for oxidative metabolism. Iron depletion also decreases the oxidative capacity of muscle by diminishing the mitochondrial content of cytochromes and other iron-dependent enzymes required for electron transport and ATP synthesis (see Function) (35).

Poor thyroid function and impaired thyroid hormone synthesis likely disrupt the ability to maintain a normal body temperature on exposure to cold in iron-deficient individuals (see Function). Iron deficiency may also impair neutrophil phagocytosis and microbicidal activity and T-lymphocyte proliferative responses to infection (1). Severe iron-deficiency anemia may result in brittle and spoon-shaped nails, sores at the corners of the mouth, taste bud atrophy, and a sore tongue. In rare cases, advanced iron-deficiency anemia may cause difficulty in swallowing due to the formation of webs of tissue in the throat and esophagus due to a degradation of the pharyngeal muscles (36). The development of esophageal webs, also known as Plummer-Vinson syndrome, may require a genetic predisposition in addition to iron deficiency. Iron deficiency and iron-deficiency anemia in early childhood have been shown to impair psychomotor development and induce short- and long-term behavioral and cognitive alterations (reviewed in 37). Further, pica, a behavioral disturbance characterized by the consumption of non-food items, may be a symptom and a cause of iron deficiency (38).

Individuals at increased risk of iron deficiency

Life stage groups with increased requirements

Neonates and infants up to six months of age: Inadequate maternal iron body stores and anemia during pregnancy may reduce the duration of gestation and birth weight; preterm and/or low body-weight newborns are at increased risk of iron-deficiency anemia (14). Pregnancy complications, including preeclampsia and gestational diabetes mellitus, may also lead to low iron stores in preterm and term infants (14).

Most of the 150 to 250 mg of iron present in a full-term healthy newborn is accumulated during the third trimester of pregnancy and is sufficient for the first four to six months of life (34). Iron stores are essential for infants less than six months of age because breast milk is relatively poor in iron (0.2 mg/L-0.4 mg/L), and intestinal absorption of iron remains low until six months of age. High iron requirements during this period of sustained and rapid growth rate can worsen the deficit in body iron in preterm infants (14). Moreover, a review of randomized controlled trials suggested that infants with an early umbilical cord clamping (≤1 min after birth) are at least twice more likely to be iron-deficient at three to six months compared to those with delayed cord clamping (39). Yet, healthy full-term infants have little need for external sources of iron before six months of age (1).

Infants and children between the ages of 6 months and 3 years: A full-term infant's iron stores are usually sufficient to last for the early months of life, but there is an increased risk of iron deficiency for infants older than six months (1). Given the sustained need of iron for increasing tissue mass, blood volume, and replenishing iron stores, the recommended dietary allowance (RDA) for iron is 11 mg/day for infants aged seven to 12 months, as established by the US Institute of Medicine (see **Table 1**).

The RDA for iron is 7 mg/day for toddlers aged 1 to 3 years old. Based on the US National Health and Nutrition Examination Survey (NHANES) 1999-2002 data, the prevalence of iron deficiency in toddlers aged 12 to 35 months varies from 6.6%-15.2%, and the prevalence of iron-deficiency anemia is 0.9%-4.4%, depending on ethnicity and socioeconomic status (14).

Of note, the World Health Organization (WHO) and the American Academy of Pediatrics recommend universal screening for anemia at one year of age. Yet, a recent report by the US Preventive Services Task Force (USPSTF) stated there was insufficient evidence to assess the benefits versus harms of screening (34, 40).

Adolescents: Early adolescence is period of rapid growth. Blood loss that occurs with menstruation in adolescent girls adds to the increased iron requirement of adolescence (1). The RDA of iron is 11 mg/day and 15 mg/day for adolescent boys and girls, respectively (see **Table 1**).

Nonpregnant women of childbearing age: Based on data from NHANES 2003-2006, the percentage of US women with two out of three markers of iron status (i.e., hemoglobin, ferritin, and % transferrin saturation) below cutoff values for deficiency was 9.8% in nonpregnant women (41).

The use of oral contraceptives decreases menstrual blood losses and is thus associated with improved iron status compared to intrauterine devices (copper coil) (1).

Breast-feeding is associated with lower dietary iron needs, allowing for the repletion of iron stores depleted during pregnancy and delivery. However, iron repletion may be incomplete in high-parity women who are therefore at increased risk of iron deficiency (41).

Pregnant women: The requirement for iron is significantly increased during pregnancy due to increased iron utilization by the developing fetus and placenta, as well as maternal blood volume expansion (42). Analysis of data from NHANES 2005-2006 found that 18.1% of pregnant women (mean age, 27.5 years) were deficient in iron, as assessed by the log ratio of soluble transferrin receptor to serum ferritin (43). The prevalence of iron deficiency was greater during the second (20.7%) and third (29.7%) trimesters compared to the first trimester (4.5%) of gestation. Further, iron deficiency in pregnancy was found to be more prevalent in Mexican (23.6%) and Black Americans (29.6%) than in non-Hispanic White Americans (13.9%) (43).

Individuals with chronic blood losses

Chronic bleeding or acute blood loss may result in iron deficiency. One milliliter (mL) of blood with a hemoglobin concentration of 150 g/L contains 0.5 mg of iron. Thus, chronic loss of very small amounts of blood may result in iron deficiency.

Parasitic infestation: A common cause of chronic blood loss and iron deficiency in developing countries is intestinal parasitic infection (44).

Frequent blood donation: Individuals who donate blood frequently, especially menstruating women, may need to increase their iron intake to prevent deficiency because each 500 mL of blood donated contains between 200 and 250 mg of iron (45, 46).

Regular intense exercise: Daily iron losses have been found to be greater in athletes involved in intense endurance training. This may be due to expanding blood cell mass and muscle mass, increased microscopic bleeding from the gastrointestinal tract (with the regular use of anti-inflammatory drugs), or increased fragility and hemolysis of red blood cells (47). The Food and Nutrition Board estimates that the average requirement for iron may be 30% higher for those who engage in regular intense exercise (25).

Individuals with decreased iron absorption

Celiac disease: Celiac disease (celiac sprue) is an autoimmune disorder estimated to occur in 1% of the population. When people with celiac disease consume food or products that contain gluten, the immune system response damages the intestinal mucosa, which may result in nutrient malabsorption and iron-deficiency anemia (48).

Atrophic gastritis: This condition is usually associated with the presence of antibodies directed towards stomach cells and has been implicated in pernicious anemia (see the article on Vitamin B_{12}). Atrophic gastritis simultaneously impairs the absorption of both vitamin B_{12} and iron; yet, in menstruating women, iron deficiency may occur years before the depletion of vitamin B_{12} body stores (47).

***Helicobacter pylori* infection**: *H. pylori* infection is associated with iron-deficiency anemia, especially in children, even in the absence of gastrointestinal bleeding. Data from NHANES 2000-2001 in individuals older than three years showed that the presence of iron deficiency (based on serum ferritin concentrations) was 40% more prevalent in those infected with *H. pylori* than in *H. pylori*-free individuals (49). Occult gastrointestinal bleeding and competition for dietary iron by bacteria may explain iron deficiency in infected individuals. Moreover, *Helicobacter pylori* infection may also play a role in the pathogenesis of atrophic gastritis (47).

Inflammatory bowel diseases (IBD): Iron-deficiency anemia is commonly reported among patients with IBD (e.g., ulcerative colitis, Crohn's disease), likely due to both impaired intestinal absorption of iron and blood loss from ulcerated mucosa (50).

Gastric bypass surgery: Some types of gastric bypass (bariatric) surgery increase the risk of iron deficiency by causing malabsorption of iron, among other nutrients (51).

Obesity: An inverse association between body weight and iron status has been reported in several observational studies in children and adults (52, 53). Higher hepcidin expression in obese people may impair iron absorption despite adequate dietary intake of iron. Weight loss might lower serum hepcidin concentration and improve iron status in obese individuals (9).

Anemia of chronic disease: Acute and chronic inflammation may lead to abnormally low circulating concentrations of iron and to the development of anemia. This type of anemia of inflammation, also known as anemia of chronic disease (ACD), is commonly observed in inflammatory disorders, cancer, critical illness, trauma, chronic infection, and parasitic infestation. It is thought that anemia develops because dietary iron absorption and iron mobilization from body stores are inhibited by inflammation-induced hepcidin up-regulation (see also Systemic regulation of iron homeostasis) (9).

Other causes of iron deficiency

Vegetarian diet with inadequate sources of iron: Because iron from plants (nonheme iron) is less efficiently absorbed than that from animal sources (see Sources), the US Food and Nutrition Board (FNB) of the Institute of Medicine (IOM) estimated that the bioavailability of iron from a vegetarian diet was only 10% versus 18% from a mixed Western diet. Therefore, the recommended dietary allowance (RDA) of iron for individuals consuming a completely vegetarian diet may be 1.8 times higher than the RDA for non-vegetarians (25). Yet, a vegetarian diet does not appear to be associated with an increased risk of iron deficiency when it includes whole grains, legumes, nuts, seeds, dried fruit, iron-fortified cereal, and green leafy vegetables (see Sources) (54).

Chronic kidney disease (CKD): Iron losses in CKD patients are due to significant gastrointestinal blood loss (1.2 L blood loss/year corresponding to ~400 mg iron/year) compared to individuals with normal kidney function (0.83 mL blood loss/day corresponding to ~100 mg iron/year). Estimated blood losses are even larger in patients on hemodialysis, and iron losses may be 1,000 to 2,000 mg/year or higher. Persistent inflammation in CKD patients may also contribute to inadequate iron supply for red blood cell formation despite adequate body iron stores (55).

The Recommended Dietary Allowance (RDA)

The RDA for iron was revised in 2001 and is based on the prevention of iron deficiency and maintenance of adequate iron stores in individuals eating a mixed diet (**Table 1**; 25).

Table 1. Recommended Dietary Allowance (RDA) for Iron

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	0.27 (AI)	0.27 (AI)
Infants	7-12 months	11	11
Children	1-3 years	7	7
Children	4-8 years	10	10
Children	9-13 years	8	8
Adolescents	14-18 years	11	15
Adults	19-50 years	8	18
Adults	51 years and older	8	8
Pregnancy	all ages	-	27
Breast-feeding	18 years and younger	-	10
Breast-feeding	19 years and older	-	9

Disease Prevention

Prevention or alleviation of iron deficiency or iron-deficiency anemia can limit the impact of iron inadequacy and defective erythropoiesis on the following health conditions and diseases.

Impaired psychomotor, cognitive, and intellectual development in children

Iron is critical for the development of the central nervous system, and iron deficiency is thought to be especially detrimental during the prenatal and early postnatal periods. Iron-dependent enzymes are required for nerve myelination, neurotransmitter synthesis, and normal neuronal energy metabolism (56). Most observational studies have found relationships between iron deficiency — with or without anemia — in children and poor cognitive development, poor school achievement, and abnormal behavior patterns (reviewed in 37). Whether psychomotor and mental deficits may be attributed to the lack of iron, only, or to a combination effect of iron deficiency and low hemoglobin concentrations — like in iron-deficiency anemia and anemia of inflammation — in early childhood remains unclear (14).

A recent systematic review of six small placebo-controlled trials (published between 1978 and 1989) in children with iron-deficiency anemia younger than 27 months found no convincing evidence that iron therapy (for less than 11 days) had any consistent effect on measures of psychomotor and mental development within 30 days of treatment initiation (57). Only one randomized, double-blind trial in anemic, iron-deficient infants examined the impact of iron therapy for four months and found a significant benefit on indices of cognitive development that needs to be further confirmed (58). A review of five randomized controlled trials in non-anemic, iron-deficient infants (0-9 months old) suggested an improvement in psychomotor (but not mental) development throughout the first 18 months of life (59). Iron supplementation in early infancy (4 to 6 months) also failed to demonstrate any long-term effect on cognitive performance and school performance at the age of 9 years compared to placebo (60). At present, evidence supporting any benefits of iron therapy on neurodevelopment outcomes in infants with iron deficiency, with or without anemia, remains limited.

Iron therapy might be more effective at improving cognitive outcomes in older children with anemia and/or iron deficiency. A systematic review of 17 randomized controlled trials found that iron supplementation had no effect on mental development of children under the age of 27 months but modestly improved scores of mental development in children over seven years of age (61). A more recent meta-analysis of randomized controlled trials in children older than six years, adolescents, and women with iron deficiency, anemia, or iron-deficiency anemia suggested that supplemental iron could improve attention and concentration irrespective of participants' iron status (62). A potential improvement in IQ measures with iron therapy was also reported in anemic participants regardless of their iron status. No additional benefits were observed regarding measures of memory performance, psychomotor function, and school achievements.

Alterations in brain functions due to iron deficiency are likely to be resistant to iron therapy when they occur in early childhood. Long-term consequences of early life iron deficiency may include poor socioeconomic achievements and increased risk of certain psychopathologies, including anxiety, depression, and schizophrenia (56).

Adverse pregnancy outcomes

Epidemiological studies provide strong evidence of an association between severe anemia in pregnant women and adverse pregnancy outcomes, such as low birth weight, preterm birth, and neonatal and maternal mortality (63). Although iron deficiency can be a major contributing factor to severe anemia, evidence that iron-deficiency anemia causes poor pregnancy outcomes is still lacking. In addition, iron supplementation during pregnancy was shown to improve iron status and hematological parameters in women but failed to significantly reduce adverse pregnancy outcomes, including low birth weight and/or prematurity, neonatal death, and congenital anomalies (64). Moreover, routine supplementation during pregnancy had no effect on the length of gestation or newborn Apgar scores (40). Nevertheless, most experts consider the control of maternal anemia to be an important part of prenatal health care, and the IOM recommends screening for anemia in each trimester of pregnancy (65).

The requirement for iron is greatly increased in the second and third trimesters, and the RDA for pregnant women is 27 mg/day of iron (see The Recommended Dietary Allowance) (25). The American College of Obstetricians and Gynecologists recommend screening all pregnant women for anemia and advise iron supplementation when required (66). Nonetheless, the US Preventive Services Task Force (40) and the American Academy of Family Physicians (67) consider that evidence is lacking to evaluate the harms and benefits of screening for iron-deficiency anemia and supplementing with iron during pregnancy.

In malaria-endemic regions, however, iron supplementation may improve pregnancy outcomes when provided in conjunction with measures of prevention and management of malaria. Two recent randomized, placebo-controlled trials failed to find an increased risk of malaria infection in both iron-deficient and iron-replete pregnant women supplemented with iron, supporting the use of universal iron supplementation in malaria-endemic countries that adopt malaria intermittent preventive treatment (IPT) (68, 69).

Lead toxicity

Children who are chronically exposed to lead, even in small amounts, are more likely to develop learning disabilities, behavioral problems, and have low IQs. Deficits in growth and neurologic development may occur in the infants of women exposed to lead during pregnancy and lactation. In adults, lead toxicity may result in kidney damage and high blood pressure. Although the use of lead in paint products, gasoline, and food cans has been discontinued in the US, lead toxicity continues to be a significant health problem, especially in children living in inner cities (70). In 2012, the US Centers for Disease Control and Prevention set the reference value for blood lead concentration at 5 micrograms per deciliter (μg/dL) to identify children at risk. Yet, there is no known blood lead concentration below which children are 100% safe (71).

Iron deficiency and lead poisoning share a number of the same risk factors, including low socioeconomic status, ethnic minority groups, and residence in urban areas. Iron deficiency may increase the risk of lead poisoning in children, especially by increasing the intestinal absorption of lead via the DMT1 intestinal transporter (72). However, the use of iron supplementation in lead poisoning might be reserved for children who are truly iron deficient or for iron-replete children with chronic lead exposure (e.g., living in lead-exposed housing) (72).

Disease Treatment

Restless legs syndrome

Restless legs syndrome (RLS; also called Willis-Ekbom disease) is a neurologic movement disorder of unknown etiology. People with RLS experience unpleasant sensations resulting in an irresistible urge to move their legs and transient relief with movement. These sensations are more common at rest and often interfere with sleep (73). The prevalence of RLS is higher in women than in men and increases with age (74). This syndrome appears to be inherited in about 50% of patients but has also been related to chronic kidney failure (73). Iron deficiency may be involved in RLS development, possibly by affecting the activity of tyrosine hydroxylase, a rate limiting iron-dependent enzyme in the synthesis of the neurotransmitter, dopamine (74). The management of RLS includes iron therapy and the use of drugs like dopamine agonists (73). Current clinical evidence is insufficient to evaluate whether iron therapy may help relieve some RLS symptoms (74). Yet, the Medical Advisory Board of the Willis-Ekbom Disease Syndrome Foundation suggests that iron status should be assessed in all patients with RLS, and iron therapy be attempted on a case-by-case basis in those who might benefit from it (73).

Sources

Food sources

The amount of iron in food or supplements that is absorbed and used by the body is influenced by the iron nutritional status of the individual and whether or not the iron is in the form of heme. Because it is absorbed by a different mechanism than nonheme iron, heme iron is more readily absorbed and its absorption is less affected by other dietary factors (2). In an attempt to improve body iron status, iron absorption is enhanced in individuals who are anemic or iron deficient compared to iron-replete individuals.

Heme iron

Heme iron comes mainly from hemoglobin and myoglobin in meat, poultry, and fish. Although heme iron accounts for only 10%-15% of the iron found in the diet, it may provide up to one-third of total absorbed dietary iron (54). The absorption of heme iron is less influenced by other dietary factors than that of nonheme iron (27).

Nonheme iron

Plants, dairy products, meat, and iron salts added to food and supplements are all sources of nonheme iron. The absorption of nonheme iron is strongly influenced by enhancers and inhibitors present in the same meal (27).

Enhancers of nonheme iron absorption

- **Vitamin C (ascorbic acid)**: Vitamin C strongly enhances the absorption of nonheme iron by reducing dietary ferric iron (Fe^{3+}) to ferrous iron (Fe^{2+}) and forming an absorbable, iron-ascorbic acid complex (75).
- **Other organic acids**: Citric, malic, tartaric, and lactic acids have some enhancing effects on nonheme iron absorption (1).
- **Meat, poultry, and fish**: Aside from providing highly absorbable heme iron, meat, fish, and poultry also enhance nonheme iron absorption. The mechanism for this enhancement of nonheme iron absorption is not clear (1, 25).

Inhibitors of nonheme iron absorption

- **Phytic acid (phytate)**: Phytic acid, present in legumes, whole grains, nuts, and seeds, inhibits nonheme iron absorption, probably by binding to it. Small amounts of phytic acid (5 to 10 mg) can reduce nonheme iron absorption by 50%. The absorption of iron from legumes, such as soybeans, black beans, lentils, mung beans, and split peas, has been shown to be as low as 2% (25). Food preparation, including soaking, germination, fermentation, and cooking, can help remove or degrade phytic acid (27).
- **Polyphenolic compounds**: Polyphenolic compounds in coffee, black tea, and herbal tea can markedly inhibit the absorption of nonheme iron (76). This effect may be reduced by the presence of vitamin C (27, 77).
- **Soy protein**: Soy protein, such as that found in tofu, has an inhibitory effect on iron absorption that is only partly related to its phytic acid content (27, 77).
- **Calcium**: Calcium appears to affect iron absorption from both heme and nonheme sources. Yet, its effect appears to be limited when one consumes a wide variety of food with varied levels of enhancers and inhibitors of iron absorption (27).

National surveys in the US have indicated that the average dietary intake of iron is 16 to 18 mg/day in men, 12 mg/day in pre- and postmenopausal women, and about 15 mg/day in pregnant women (25). Thus, the majority of premenopausal and pregnant women in the US consume less than the RDA for iron, and many men consume more than the RDA (see The Recommended Dietary Allowance). In the US, most grain products are fortified with nonheme iron. The iron content of some relatively iron-rich foods is listed in milligrams (mg) in **Table 2**. For more information on the nutrient content of specific foods, search USDA's FoodData Central.

Table 2. Some Food Sources of Iron

Food	Serving	Iron (mg)
Beef	3 ounces*	1.6
Chicken, liver, cooked, pan-fried	1 ounce	3.6
Oysters, Pacific, cooked	6 medium	13.8
Oysters, Eastern, cooked	6 medium	3.9
Clams, cooked, steamed	3 ounces	2.4
Tuna, light, canned in water	3 ounces	1.3

Mussels, cooked, steamed	3 ounces	5.7
Raisin bran cereal	1 cup	5.8-18.0
Raisins, seedless	1 small box (1.5 ounces)	0.8
Prune juice	6 fluid ounces	2.3
Prunes (dried plums)	~5 prunes (1.7 ounces)	0.4
Potato, with skin, baked	1 medium potato	1.8
Quinoa, cooked	½ cup	1.4
Spinach, cooked	1 cup	6.4
Swiss chard, cooked, boiled	½ cup	2.0
Beans, white, cooked	½ cup	3.3
Lentils, cooked	½ cup	3.3
Tofu, regular, raw	½ cup	6.6
Hazelnuts, dry-roasted	1 ounce	1.3
Cashews	1 ounce	1.9
*A three-ounce serving of meat is about the size of a deck of cards.		

Supplements

Iron supplements are indicated for the prevention and treatment of iron deficiency and iron deficiency anemia. Individuals who are not at risk of iron deficiency (e.g., adult men and postmenopausal women) should not take iron supplements without an appropriate medical evaluation. A number of iron supplements are available, and different forms provide different proportions of elemental iron. Ferrous sulfate heptahydrate is 20% elemental iron, ferrous sulfate monohydrate is 33% elemental iron, ferrous gluconate is 12% elemental iron, and ferrous fumarate is 33% elemental iron. If not stated otherwise, the iron discussed in this article is elemental iron.

Iron Overload

Deregulation of intestinal iron absorption will result in iron overload because the body cannot excrete excess iron (2). However, iron overload due to prolonged iron supplementation is very rare in healthy individuals without a genetic predisposition. Several genetic disorders may lead to pathological accumulation of iron in the body despite normal iron intake. Supplementation of individuals who are not iron deficient should be avoided due to the frequency of undetected inherited diseases and recent concerns about the more subtle effects of chronic excess iron intake (see Diseases associated with iron overload).

Inherited iron-overload diseases

Hereditary hemochromatosis

Hereditary hemochromatosis (HH) refers to late-onset, autosomal recessive disorders of iron metabolism that result in iron accumulation in the liver, heart, and other tissues. Disorders may lead to cirrhosis of the liver, diabetes mellitus, cardiomyopathy (heart muscle damage), hypogonadism, arthropathy (joint problems), and increased skin pigmentation (reviewed in 78). There are four main types of HH, which are classified according to the specific gene that is mutated. The most common type of HH, called Type 1 or *HFE*-related HH, results from mutations in the *HFE* gene (79, 80). The majority of Type 1 HH cases are homozygous for mutation C282Y G>A (rs1800560) in the *HFE* gene. Another mutation found in 4% of patients with Type 1 HH is H63D C>G (rs1799945) in the *HFE* gene. The protein encoded by the *HFE* gene is thought to play a role in regulating intestinal absorption of dietary iron and with sensing the body's iron stores (81). *HFE* gene mutations are associated with an increased cellular uptake of iron. With a typical disease onset before age 30, juvenile hemochromatosis (HH Type 2) is much rarer than Type 1 HH and results from genetic mutations affecting either hemojuvelin (Type 2A) or hepcidin (Type 2B) function (82). HH Type 3 results from mutations in the transferrin receptor 2 gene (*TFR2*), and HH Type 4 (also called Ferroportin disease) results from mutations in the gene encoding ferroportin-1 (*SLC40A1*), a protein important in the export of iron from cells (see Regulation). Type 4 HH is the second most common inherited iron overload disorder after Type 1 HH (78).

Iron overload in HH is treated by phlebotomy, the removal of 500 mL of blood at a time, at intervals determined by the severity of the iron overload. Chelation therapy is an alternate option to deplete iron in HH patients who cannot undergo phlebotomy treatment. Individuals with HH are advised to avoid supplemental iron, but generally not told to avoid iron-rich food. High-dose vitamin C regimens may worsen iron overload in patients with HH (75). Alcohol consumption is strongly discouraged due to the increased risk of cirrhosis of the liver (83). Genetic testing, which requires a blood sample, is available for those who may be at risk for HH, for example, individuals with a family history of hemochromatosis.

Other inherited conditions

Other genetic disorders leading to iron overload include aceruloplasminemia, hypotransferrinemia, Friedreich's ataxia, and porphyria cutanea tarda (2).

Acquired iron-overload diseases

Iron overload may develop in individuals with severe hereditary anemias that are not caused by iron deficiency. Excessive dietary absorption of iron may occur in response to the body's continued efforts to form red blood cells. Beta-thalassemia is characterized by defective hemoglobin A synthesis due to mutations in the β-globin gene. Patients affected by thalassemia intermedia do not require blood transfusion as do those affected by the most severe form of the disease (called thalassemia major), yet they develop iron overload due to increased intestinal iron absorption (84). Other anemic patients at risk of iron overload include those with sideroblastic anemia, hemolytic anemia, pyruvate kinase deficiency, and thalassemia major, especially because they are treated with numerous transfusions. Patients with hereditary spherocytosis and thalassemia minor do not usually develop iron overload unless they are misdiagnosed as having iron deficiency and treated with large doses of iron over many years. Iron overload has also been associated with hemodialysis and chronic liver diseases (metabolic, viral, and alcoholic) (2).

Diseases associated with iron overload

Toxic iron deposition in vital organs in hereditary hemochromatosis (HH) has been associated with an increased incidence of liver cancer, type 2 diabetes mellitus, and neurodegenerative disease. Iron overload might also increase the risk of chronic disease in HH-free individuals. Nevertheless, whether iron tissue accumulation in those unaffected by genetic disorders is due to high dietary iron intakes is not yet fully understood (1).

Cancer

Hereditary hemochromatosis that is characterized by abnormal hepatic iron accumulation is a risk factor for liver cancer (hepatocellular carcinoma; HCC). Iron accumulation is thought to function as a carcinogen by increasing oxidative stress that causes damage to lipids, proteins, and DNA. A meta-analysis of nine observational studies found an increased HCC risk with the C282Y mutation in the *HFE* gene of healthy participants and patients with chronic liver disease (see Iron Overload) (85). Other meta-analyses have reported associations between *HFE* gene mutations C282Y and H63D and increased risks of overall cancer (86, 87). However, studies reporting on *HFE* gene mutations and risk of cancer at extra-hepatic sites are rather scarce and/or inconsistent. Some, but not all, observational studies found significant associations between the C282Y mutation and risk of colorectal (88), breast (88, 89), and epithelial ovarian cancer (90). The presence of the H63D mutation in the *HFE* gene was linked to an increased risk of leukemia (91, 92) and gastric cancer (93).

Whether high dietary iron could increase the risk of cancer in individuals without hemochromatosis has also been investigated. The consumption of red or processed meat (but not white meat), rich in heme iron, has been linked to an increased risk of colorectal cancer (CRC) (94). Exposure to carcinogenic compounds (called heterocyclic amines) generated when meat is cooked at high temperatures and to carcinogenic N-nitroso compounds formed in the gastrointestinal tract following consumption of red and processed meat may explain such an association (95). Several meta-analyses of observational studies have also suggested a potential association of heme iron in red meat with CRC (96-98). This has been explained by an increased exposure of colonic cells to potentially damaging N-nitroso compounds and lipid peroxidation end-products derived from heme iron-catalyzed reactions (99). Further, recent results from the large European Prospective Investigation into Cancer and Nutrition (EPIC) study suggested a higher risk of esophageal adenocarcinoma with high intakes of red/processed meat and heme iron (100).

Cardiovascular disease

Experimental studies have suggested a role for iron-induced oxidative stress in vessel wall damage and the development of atherosclerosis, which underlies most forms of cardiovascular disease (101). However, epidemiological studies of iron nutritional status and cardiovascular disease in humans have yielded conflicting results. A recent systematic review and meta-analysis of 17 prospective cohort studies in 156,427 participants (9,236 cases of coronary heart disease [CHD] or myocardial infarction [MI]) did not find evidence to support the existence of strong associations between a number of different measures of iron status and CHD/MI (102). Only individuals in the highest versus lowest tertile of serum transferrin saturation exhibited an 18% lower incidence of CHD/MI (102). Another meta-analysis of 21 prospective studies found serum transferrin saturation and serum iron to be inversely associated with the risk of CHD. However, the authors noted that most studies failed to adjust for the confounding effects of inflammation (103). The review also reported an inverse association between CHD incidence and total dietary iron intake, but dietary heme iron was positively associated with CHD incidence (103). Although the relationship between iron stores and CHD/MI requires further clarification, it would be prudent for those who are not at risk of iron deficiency (e.g., adult men and postmenopausal women) to avoid excess iron intake (see the LPI Rx for Health).

Type 2 diabetes mellitus and metabolic syndrome

Individuals with hereditary hemochromatosis (HH) are known to be at a heightened risk of developing type 2 diabetes mellitus (104). Increasing evidence also suggests a role for iron excess in the pathogenesis of type 2 diabetes independent of hemochromatosis. Cross-sectional, case-control, and prospective cohort studies have reported an increased risk of type 2 diabetes (105) and metabolic syndrome (106) with high versus low ferritin concentrations (reflecting iron body stores) after adjustment for inflammation. It is currently unclear how other indices of iron status relate to the risk of type 2 diabetes (107-110). Iron overload-induced oxidative stress in patients with HH is thought to damage pancreatic β-cells and impair insulin secretion. In subjects free of HH, iron excess might damage the liver, interfering with glucose metabolism and triggering insulin resistance, rather than impair β-cell function (111, 112). Iron removal by phlebotomy has been shown to improve metabolic parameters in subjects with type 2 diabetes (113) and metabolic syndrome (114). Additional randomized controlled trials are needed to determine whether lowering body stores of iron will aid in the prevention of type 2 diabetes and metabolic syndrome.

Neurodegenerative disease

Iron is required for normal brain and nerve function through its involvement in cellular metabolism, as well as in the synthesis of neurotransmitters and myelin. Deregulation of iron homeostasis has been observed in a number of neurodegenerative diseases, including Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis (ALS; Lou Gehrig's disease) (115-117). The abnormal accumulation of iron in the brain does not appear to be a result of increased dietary iron, but rather a disruption in the complex process of cellular iron regulation (117). Brain iron accumulation can result in increased oxidative stress, and the brain is particularly susceptible to oxidative damage. Mechanisms behind the disruption of iron homeostasis in the brain of patients affected by neurodegenerative disease are actively being investigated. For example, studies using genetically modified mouse models indicated that the suppression of amyloid precursor protein (APP) expression by upstream nitric oxide (NO) elevation (11) or loss of Tau protein (12) could impair neuronal export of iron and lead to iron accumulation in specific brain regions affected in Parkinson's disease. A pilot, double-blind, placebo-controlled trial in patients with early-stage Parkinson's disease demonstrated oral administration of the iron chelator, deferiprone, for 12 months reduced iron deposition in the part of the brain called substantia nigra and improved motor performance without compromising systemic iron homeostasis (118, 119).

Safety

Toxicity

Overdose

Accidental overdose of iron-containing products is the single largest cause of poisoning fatalities in children under six years of age. Although the oral lethal dose of elemental iron is approximately 180 to 250 mg/kg of body weight, considerably less has been fatal. Symptoms of acute toxicity may occur with iron doses of 20 to 60 mg/kg of body weight. Iron overdose is an emergency situation because the severity of iron toxicity is related to the amount of elemental iron absorbed. Acute iron poisoning produces symptoms in four stages: (1) Within one to six hours of ingestion, symptoms may include nausea, vomiting, abdominal pain, tarry stools, lethargy, weak and rapid pulse, low blood pressure, fever, difficulty breathing, and coma; (2) If not immediately fatal, symptoms may subside for about 24 hours; (3) Symptoms may return 12 to 48 hours after iron ingestion and may include serious signs of failure in the following organ systems: cardiovascular, kidney, liver, hematologic (blood), and central nervous system; and (4) Long-term damage to the central nervous system, liver (cirrhosis), and stomach may develop two to six weeks after ingestion (25, 120).

Adverse effects

At therapeutic levels used to treat iron deficiency, iron supplements may cause gastrointestinal irritation, nausea, vomiting, diarrhea, or constipation. Stools will often appear darker in color. Iron-containing liquids can temporarily stain teeth, but diluting the liquid helps to prevent this effect (120). Taking iron supplements with food instead of on an empty stomach may relieve gastrointestinal effects. The Food and Nutrition Board (FNB) of the Institute of Medicine based the tolerable upper intake level (UL) for iron on the prevention of gastrointestinal distress (**Table 3**). The UL for adolescents (14-18 years) and adults, including pregnant and breast-feeding women, is 45 mg/day. It should be noted that the UL is not meant to apply to individuals being treated with iron under close medical supervision. Individuals with hereditary hemochromatosis or other conditions of iron overload, as well as individuals with alcoholic cirrhosis and other liver diseases, may experience adverse effects at iron intake levels below the UL (25).

Table 3. Tolerable Upper Intake Level (UL) for Iron

Age Group	UL (mg/day)
Infants 0-12 months	40
Children 1-13 years	40
Adolescents 14-18 years	45
Adults 19 years and older	45

Drug interactions

Medications that decrease stomach acidity, such as antacids, histamine (H_2) receptor antagonists (e.g., cimetidine, ranitidine), and proton-pump inhibitors (e.g., omeprazole, lansoprazole), may impair iron absorption. Taking iron supplements at the same time as the following medications may result in decreased absorption and efficacy of the medication: carbidopa and levodopa (Sinemet), levothyroxine (Synthroid, Levoxyl), methyldopa (Aldomet), penicillamine (Cuprimine, Depen), quinolones, tetracyclines, and bisphosphonates (120). Therefore, it is best to take these medications two hours apart from iron supplements. Cholestyramine (Questran) and colestipol (Colestid), used to lower blood cholesterol concentrations, should also be taken at least four hours apart from iron supplements because they may interfere with iron absorption (121).

Does iron supplementation increase the risk of malaria in malaria-endemic regions?

Despite the critical functions of iron in the immune response, the nature of the relationship between iron status and susceptibility to infection, especially with respect to malaria, has been controversial. Because iron withholding is a recognized defense mechanism against pathogens (see Iron withholding defense during infection), concerns have been raised regarding the safety of iron supplementation, especially in iron-replete children living in malaria-endemic regions (122).

Iron supplementation of children residing in the tropics has been associated with increased risk of clinical malaria and other infections like pneumonia (123, 124). A randomized controlled trial in 24,076 children (ages, 1-35 months) living in a malaria-endemic region of eastern Africa (Tanzania) investigated the effects of supplemental iron and folic acid, with or without zinc, compared to the effects of zinc alone or a placebo, on all-cause mortality and hospital admissions (125). The administration of iron, folic acid, and/or zinc was found to increase the risk of serious adverse effects, hospital admission, and death, and was therefore prematurely halted. Further analyses of the trial revealed that iron-replete children were more likely than iron deficient-children (with or without anemia) to be at risk of adverse effects following iron supplementation (125). Such a potential risk of adverse effects with routine iron supplementation was not observed in preschool children in settings without malaria (southern Nepal) (126).

A recent review of 35 trials indicated that iron supplementation did not increase the risk of clinical malaria or other parasitic diseases, infections, and all-cause mortality in children living in malaria-endemic regions in which prevention and management of malaria are available (127). Moreover, a pooled analysis of three high-quality trials demonstrated that supplemental iron combined with anti-malarial treatment protected children against clinical malaria and improved hematological parameters (127). The World Health Organization (WHO) currently recommends the provision of iron supplementation in infants and children, together with measures of malaria prevention, diagnosis, and treatment in malaria-endemic areas (128).

Linus Pauling Institute Recommendation

Following the RDA for iron should provide sufficient iron to prevent deficiency without causing adverse effects in most individuals. Although sufficient iron can be obtained through a varied diet, a considerable number of people do not consume adequate iron to prevent deficiency. A multivitamin/mineral supplement containing 100% of the daily value (DV) for iron provides 18 mg of elemental iron. While this amount of iron may be beneficial for premenopausal women, it is well above the RDA for men and postmenopausal women.

Adult men and postmenopausal women

Since hereditary hemochromatosis is not uncommon and the effects of long-term dietary iron excess on chronic disease risk are not yet clear, men and postmenopausal women who are not at risk of iron deficiency should take a multivitamin/mineral supplement without iron. A number of multivitamins formulated specifically for men or those over 50 years of age do not contain iron.

Older adults (>50 years)

Moderately elevated iron stores might be much more common than iron deficiency in middle-age and older individuals (129). Thus, older adults should not generally take nutritional supplements containing iron unless they have been diagnosed with iron deficiency. Moreover, it is extremely important to determine the underlying cause of the iron deficiency, rather than simply treating it with iron supplements (see The Recommended Dietary Allowance).

Summary

- Magnesium is an essential mineral and a cofactor for hundreds of enzymes. Magnesium is involved in many physiologic pathways, including energy production, nucleic acid and protein synthesis, ion transport, cell signaling, and also has structural functions. *(More information)*
- Severe magnesium deficiency can impede vitamin D and calcium homeostasis. Certain individuals are more susceptible to magnesium deficiency, especially those with gastrointestinal or renal disorders, those suffering from chronic alcoholism, and older people. *(More information)*
- Inadequate dietary intakes and/or low serum concentrations of magnesium have been associated with increased risk of cardiovascular disease, osteoporosis, and metabolic disorders, including metabolic syndrome, hypertension, and type 2 diabetes mellitus. Preliminary studies have shown that magnesium improved insulin sensitivity in individuals at risk for type 2 diabetes mellitus. Randomized controlled trials have also investigated the role of magnesium supplementation in the prevention of complications following stroke or heart surgery. *(More information)*
- Magnesium sulfate is used in obstetric care for the prevention of seizures in pregnant women with preeclampsia or eclampsia. Observational studies and randomized controlled trials also support a role for magnesium in preventing brain damage in premature infants. *(More information)*
- The use of magnesium supplementation is currently being explored in the management of various conditions, including hypertension, cardiovascular disease, type 2 diabetes mellitus, asthma and pain. *(More information)*
- About half of the US adult population may have insufficient magnesium intakes to support nutritional adequacy. Dietary sources rich in magnesium include green leafy vegetables, unrefined grains, legumes, beans, and nuts. *(More information)*
- The tolerable upper intake level (UL) for supplemental magnesium is 350 mg/day. Excessive intake of supplemental magnesium can result in adverse effects, especially in individuals with impaired kidney functions. *(More information)*

Magnesium plays important roles in the structure and the function of the human body. The adult human body contains about 25 grams (g) of magnesium. About 50 to 60% of all the magnesium in the body is found in the skeleton and the remainder is found in soft tissue, primarily in muscle. Magnesium is the second most abundant intracellular cation after potassium. Blood contains less than 1% of total body magnesium. Only the free, ionized form of magnesium (Mg^{2+}) is physiologically active. Protein-bound and chelated magnesium serve to buffer the pool of free, ionized magnesium (1).

Function

Magnesium is involved in more than 300 essential metabolic reactions, some of which are discussed below (2).

Energy production

The metabolism of carbohydrates and fats to produce energy requires numerous magnesium-dependent chemical reactions. Magnesium is required by the adenosine triphosphate (ATP)-synthesizing protein in mitochondria. ATP, the molecule that provides energy for almost all metabolic processes, exists primarily as a complex with magnesium (MgATP) (3).

Synthesis of essential molecules

Magnesium is required for a number of steps during synthesis of deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and proteins. Several enzymes participating in the synthesis of carbohydrates and lipids require magnesium for their activity. Glutathione, an important antioxidant, requires magnesium for its synthesis (3).

Structural roles

Magnesium plays a structural role in bone, cell membranes, and chromosomes (3).

Ion transport across cell membranes

Magnesium is required for the active transport of ions like potassium and calcium across cell membranes. Through its role in ion transport systems, magnesium affects the conduction of nerve impulses, muscle contraction, and normal heart rhythm (3).

Cell signaling

Cell signaling requires MgATP for the phosphorylation of proteins and the formation of the cell-signaling molecule, cyclic adenosine monophosphate (cAMP). cAMP is involved in many processes, including the secretion of parathyroid hormone (PTH) from the parathyroid glands (see the articles on Vitamin D and Calcium for information on the role of PTH in the body) (3).

Cell migration

Calcium and magnesium concentrations in the fluid surrounding cells affect the migration of a number of different cell types. Such effects on cell migration may be important in wound healing (3).

Nutrient interactions

Zinc

High doses of zinc in supplemental form apparently interfere with the absorption of magnesium. One study reported that zinc supplements of 142 mg/day (well above the tolerable upper intake level (UL) of 40 mg/day for zinc) in healthy adult males significantly decreased magnesium absorption and disrupted magnesium balance (the difference between magnesium intake and magnesium loss) (4).

Fiber

Large increases in the intake of dietary fiber have been found to decrease magnesium utilization in experimental studies. However, the extent to which dietary fiber affects magnesium nutritional status in individuals with a varied diet outside the laboratory is not clear (2, 3).

Protein

Dietary protein intake may affect magnesium absorption. One study in adolescent boys found that magnesium absorption was directly related to protein intake, with magnesium absorption the lowest when protein intake was less than 30 g/day (5).

Vitamin D and calcium

The active form of vitamin D (calcitriol) may slightly increase intestinal absorption of magnesium (6). However, it is not clear whether magnesium absorption is calcitriol-dependent as is the absorption of calcium and phosphate. High calcium intake has not been found to affect magnesium balance in most studies. Inadequate blood magnesium concentrations are known to result in low blood calcium concentrations, resistance to parathyroid hormone (PTH) action, and resistance to some of the effects of vitamin D (2, 3).

Deficiency

Risk factors

Magnesium deficiency in healthy individuals who are consuming a balanced diet is quite rare because magnesium is abundant in both plant and animal foods and because the kidneys are able to limit urinary excretion of magnesium when intake is low. The following conditions increase the risk of magnesium deficiency (7):

- Gastrointestinal disorders: Prolonged diarrhea, Crohn's disease, malabsorption syndromes, celiac disease, surgical removal of a portion of the small intestine, and intestinal inflammation due to radiation may all lead to magnesium depletion.
- Renal disorders (magnesium wasting): Diabetes mellitus and long-term use of certain diuretics (see Drug interactions) may result in increased urinary loss of magnesium. Multiple other medications can also result in renal magnesium wasting (3).
- Endocrine and metabolic disorders: Several conditions, such as diabetes mellitus, parathyroid gland disorders, phosphate depletion, primary aldosteronism, and even excessive lactation, can lead to magnesium depletion.

Poor dietary intake, gastrointestinal problems, and increased urinary loss of magnesium may all contribute to magnesium depletion in people suffering from alcoholism. Older adults have relatively low dietary intakes of magnesium (8, 9). Intestinal magnesium absorption tends to decrease with age, and urinary magnesium excretion tends to increase with age; thus, suboptimal dietary magnesium intake may increase the risk of magnesium depletion in the elderly (2).

Signs and symptoms

Although severe magnesium deficiency is uncommon, it has been induced experimentally. When magnesium deficiency was induced in humans, the earliest sign was a decrease in serum magnesium concentration. Hypomagnesemia usually describes serum magnesium concentrations less than 0.74 millimoles/liter (mmol/L) or 1.40 milliequivalents/liter (mEq/L) or 1.70 milligrams/deciliter (mg/dL). Over time, serum calcium concentration also began to decrease (hypocalcemia) despite adequate dietary calcium. Hypocalcemia persisted despite increased secretion of parathyroid hormone (PTH), which regulates calcium homeostasis. Usually, increased PTH secretion quickly results in the mobilization of calcium from bone and normalization of blood calcium concentration. As the magnesium depletion progressed, PTH secretion diminished to low concentrations. In addition to hypomagnesemia, signs of severe magnesium deficiency included hypocalcemia, low serum potassium concentrations (hypokalemia), retention of sodium, low circulating PTH concentrations, neurological and muscular symptoms (tremor, muscle spasms, tetany), loss of appetite, nausea, vomiting, and personality changes (3).

While mild magnesium deficiency may not elicit clinical symptoms, it may be associated with an increased risk of developing chronic diseases (see Disease Prevention) (1).

Assessing magnesium status

There is currently no reliable indicator of magnesium status. The magnesium tolerance test, which basically determines magnesium retention (using 24-h urine collection) following the intravenous administration of magnesium, is considered to be the gold standard (1). If this method is a good indicator of hypomagnesemia in adults, it appears to be poorly sensitive to changes in magnesium status in healthy people. Moreover, the method is invasive and cumbersome, and thus difficult to use routinely (10). Another method to assess magnesium status is through measurements of plasma ionized magnesium, which represents the physiologically active form of magnesium. However, it is unknown whether plasma ionized magnesium reflect body stores (10).

In practice, magnesium status is usually determined through assessments of dietary magnesium intake, serum magnesium concentration, and/or urinary magnesium concentration (10). However, each of these indicators has limitations. Although predominantly used in epidemiological studies and the sole indicator available to clinicians, serum magnesium concentration has been found to poorly respond to magnesium supplementation. Regarding dietary intakes of magnesium, about 30 to 40% of ingested magnesium is absorbed, yet absorption varies with the amount of magnesium ingested and with the food matrix composition. Finally, a state of magnesium deficiency has not been associated to a clear cutoff concentration of magnesium in the urine. Urinary magnesium concentration fluctuates rapidly with dietary intakes, but measurements of 24-hour urinary magnesium can be used in addition to other indicators to assess population status. Presently, a combination of all three markers — dietary, serum, and urinary magnesium — may be used to get a valid assessment of magnesium status (reviewed in 10).

The Recommended Dietary Allowance (RDA)

In 1997, the Food and Nutrition Board of the Institute of Medicine increased the Recommended Dietary Allowance (RDA) for magnesium, based on the results of tightly controlled balance studies that utilized more accurate methods of measuring magnesium (**Table 1**) (2). Balance studies are useful for determining the amount of a nutrient that will prevent deficiency; however, such studies provide little information regarding the amount of a nutrient required for chronic disease prevention or optimal health.

Table 1. Recommended Dietary Allowance (RDA) for Magnesium

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	30 (AI*)	30 (AI)
Infants	7-12 months	75 (AI)	75 (AI)
Children	1-3 years	80	80
Children	4-8 years	130	130
Children	9-13 years	240	240
Adolescents	14-18 years	410	360
Adults	19-30 years	400	310
Adults	31 years and older	420	320
Pregnancy	18 years and younger	-	400
Pregnancy	19-30 years	-	350
Pregnancy	31 years and older	-	360
Breast-feeding	18 years and younger	-	360
Breast-feeding	19-30 years	-	310
Breast-feeding	31 years and older	-	320
*Adequate Intake			

Disease Prevention

Metabolic syndrome

Metabolic syndrome refers to the concomitant presentation of several metabolic disorders in an individual, including dyslipidemia, hypertension, insulin resistance, and obesity (11). People with metabolic syndrome are at greater risk of developing type 2 diabetes mellitus, cardiovascular disease, and some types of cancer (12-14). A 2015 analysis of data from the US National Health and Nutrition Examination Survey (NHANES 2001-2010) in 9,148 adults (mean age, 50 years) found a 32% lower risk of metabolic syndrome in those in the highest versus lowest quantile of magnesium intake (≥355 mg/day versus <197 mg/day) (15). Several meta-analyses of primarily cross-sectional studies have also reported an inverse association between dietary magnesium intake and risk of metabolic syndrome (16-18). Moreover, lower serum magnesium concentrations have been reported in individuals with metabolic syndrome compared to controls (18, 19). However, circulating magnesium represents only 1% of total body stores and is tightly regulated; thus, serum magnesium concentrations do not best reflect magnesium status (1). At present, additional evidence is needed from prospectively designed studies to inform the potential relationship between dietary and circulating magnesium and the risk of metabolic syndrome.

Systemic inflammation, which contributes to the development of metabolic disorders, has been inversely correlated with magnesium intakes in a cross-sectional study of 11,686 women (≥45 years). In this study, the lowest prevalence of metabolic syndrome was found in the group of women in the highest quintile of magnesium intakes (median intake, 422 mg/day) (20). Several randomized controlled trials also reported a reduction in circulating C-reactive protein (CRP) — a marker of inflammation — following oral magnesium supplementation (21). This might constitute a potential mechanism through which magnesium could play a role in the prevention of metabolic disorders.

Cardiovascular disease

Hypertension (high blood pressure)

Large prospective cohort studies have examined the relationship between magnesium and blood pressure. However, the fact that foods high in magnesium (fruit, vegetables, whole grains) are frequently high in potassium and dietary fiber has made it difficult to evaluate the independent effect of magnesium on blood pressure. Findings from large cohorts, including the Health Professionals Follow-up Study (HPFS) (22), the Nurses' Health Study (NHS) (23), the Atherosclerosis Risk in Communities (ARIC) study (24), and the Coronary Artery Risk Development in Young Adults (CARDIA) study (25), have been summarized in a recent meta-analysis (26). The pooled analysis of seven prospective studies showed an 8% lower risk of hypertension with higher versus lower dietary magnesium intakes (26). In one of these studies, data from 5,511 men and women followed for a median period of 7.6 years found that the highest concentrations of urinary magnesium corresponded to a 25% reduction in the risk of hypertension, whereas there was no association between plasma magnesium concentrations and the risk of hypertension (27). There was also no evidence of an association between circulating magnesium concentrations and the risk of hypertension in a meta-analysis of three prospective cohort studies (26).

The relationship between magnesium intake and risk of hypertension suggests that improving diet quality or using magnesium supplements might play a role in the prevention of hypertension in those with inadequate dietary intakes.

Vascular calcification

The buildup of plaque inside arterial walls — a process called atherosclerosis — is an early event in the development of cardiovascular disease. The calcification of atherosclerotic plaques that occurs with the progression of atherosclerosis has been associated with a three- to four-fold increase in the risk of cardiovascular events and mortality (28).

Individuals with chronic kidney disease (CKD): Abnormalities in mineral and bone metabolism are not uncommon in individuals with impaired kidney function and have been associated with an increased risk of cardiovascular disease and mortality (29, 30). In particular, elevated blood phosphorus concentration and increased deposition of calcium phosphate within the vasculature are thought to promote vascular calcification. Since magnesium can function as a calcium antagonist, it has been suggested that it could be utilized to slow down or reverse the calcification of vessels observed in patients with CKD. In a cross-sectional study in patients with pre-dialysis CKD, higher serum magnesium concentrations were associated with lower coronary artery calcification density scores in those in the higher end of normal serum phosphorus concentrations (i.e., ≥3.4 mg/dL) (31). One small randomized, placebo-controlled trial in participants with pre-dialysis CKD examined the effect of oral, slow-release magnesium hydroxide on the calcification propensity of serum by measuring the time needed for primary calciprotein particles (containing amorphous calcium phosphate) to transform into secondary calciprotein particles (containing crystalline hydroxyapatite) (32). Increased serum calcification propensity has been associated with greater risk of mortality in patients with impaired kidney function (33, 34). The trial found an increase in serum magnesium concentration and a reduction in serum calcification propensity — i.e., an increase in the time needed for 50% of the transformation to occur (T_{50}) — with 720 mg/day of supplemental magnesium for eight weeks compared to placebo (32). Serum calcification propensity was also reduced when magnesium concentration was increased (from 1 to 2 mEq/L for 28 days) in the dialysate of patients with established kidney failure (35). A larger randomized controlled trial in patients with pre-dialysis CKD is underway to examine further the effect of oral magnesium on markers of vascular calcification, markers of mineral and bone metabolism, incidence of cardiovascular events, and deterioration of kidney function (36).

Individuals with normal kidney function: The cross-sectional analysis of data from 2,695 middle-aged participants in the Framingham Heart Study showed that the odds of having coronary artery calcification was 58% lower in those in the highest versus lowest quartile of total magnesium intakes (median values, 427 mg/day versus 259 mg/day) (37). Serum magnesium concentration was also found to be inversely associated with vascular calcification in recent population-based cross-sectional studies (38-40). No research has yet examined whether improving magnesium status of generally healthy people could play a role in atherosclerosis prevention.

magnesium status of generally healthy people could play a role in atherosclerosis prevention.

Risk of cardiovascular disease

Dietary magnesium intakes: Several large prospective cohort studies, including the Health Professionals Follow-up Study (HPFS) and the Nurses' Health Study (NHS), have examined magnesium intakes in relation to cardiovascular outcomes. In the most recent analysis of the NHS, which followed nearly 90,000 female nurses for 28 years, those in the highest quintile of magnesium intake had a 39% lower risk of fatal myocardial infarction (but not nonfatal coronary heart disease [CHD]) compared to those in the lowest quintile (>342 mg/day versus <246 mg/day) (41). A meta-analysis of nine prospective cohort studies, mostly conducted in participants without cardiovascular disease at baseline, reported a 22% lower risk of CHD per 200 mg/day incremental intake in dietary magnesium (42). A more recent meta-analysis by Fang et al. (43) included six studies and reported a 10% lower risk of CHD with higher versus lower dietary magnesium intakes.

Higher magnesium intakes were associated with an 8 to 11% reduction in stroke risk in two meta-analyses of prospective studies, each including over 240,000 participants (44, 45). The most recent pooled analysis of 14 studies found a 12% lower risk of stroke with higher versus lower magnesium intakes and estimated a 7% risk reduction of stroke associated with each 100-mg increment in daily magnesium intake (43).

Only two prospective studies have examined the risk of heart failure in relation to magnesium intakes. The pooled analysis suggested a 31% lower risk of heart failure with higher dietary magnesium intakes (43).

Finally, a meta-analysis of 13 prospective studies in over 475,000 participants reported that the risk of total cardiovascular events, including stroke, nonfatal myocardial infarction, and CHD, was 15% lower in individuals with higher intakes of magnesium (46). However, in the recent meta-analysis of eight studies by Fang et al. (43), there was no association between dietary magnesium intake and risk of total cardiovascular disease.

It is important to note that while these prospective cohort studies assessed the association between dietary magnesium and cardiovascular disease, they did not account for the use of supplemental magnesium by a significant fraction of participants.

Serum magnesium concentrations: One large prospective study (almost 14,000 men and women) associated higher serum magnesium concentrations with a lower risk of CHD in women but not in men (47). This study was included in a meta-analysis of four studies that showed no evidence of a reduced risk of CHD with increasing serum magnesium concentrations (42). In contrast, a 0.2 mmol/L increment in serum magnesium concentration was associated with a 30% lower risk of total cardiovascular disease in a pooled analysis of eight prospective cohort studies (42). In the recently published British Regional Heart Study that followed 3,523 men for a mean 15 years, there was no association between serum magnesium concentration and incidental CHD events, yet serum magnesium concentration was inversely associated with the risk of heart failure (48).

Cardiovascular mortality

A number of early studies found lower cardiovascular-related mortality in populations who routinely consume "hard" water. Hard (alkaline) water is generally high in magnesium but may also contain more calcium and fluoride than "soft" water, making the cardioprotective effects of hard water difficult to attribute to magnesium alone (49). Additionally, meta-analyses of prospective studies have found no associations between magnesium intake and cardiovascular (50) or all-cause mortality (43). In a prospective analysis of NHANES data from 14,353 participants, followed for a median period of 28.6 years, the risk of all-cause and stroke mortality was significantly increased in those with low rather than normal serum concentrations of magnesium (<0.7 mmol/L versus 0.8-0.89 mmol/L) (51). In contrast, hypermagnesemia (serum magnesium concentration >0.89 mmol/L) — rather than hypomagnesemia — in people with heart failure was associated with an increased risk of cardiovascular and all-cause mortality (52).

Aneurysmal subarachnoid hemorrhage

Occurrence of hypomagnesemia has been reported in patients who suffered from a subarachnoid hemorrhage (a type of stroke) caused by the rupture of a cerebral aneurysm (53). Poor neurologic outcomes following an aneurysmal subarachnoid hemorrhage (aSAH) have been linked to inappropriate calcium-dependent contraction of arteries (known as cerebral arterial vasospasm), leading to delayed cerebral ischemia (54). Because magnesium is a calcium antagonist and potent vasodilator, several randomized controlled trials have examined whether intravenous magnesium sulfate infusions could reduce the incidence of vasospasm after aSAH. A meta-analysis of nine randomized controlled trials found that magnesium therapy after aSAH significantly reduced vasospasm but failed to prevent neurologic deterioration or decrease the risk of death (55). Another meta-analysis of 13 trials in 2,413 aSAH sufferers concluded that the infusion of magnesium sulfate had no benefit regarding neurologic outcome and mortality, despite a reduction in the incidence of delayed cerebral ischemia (56). The post-hoc analysis of a small randomized controlled trial suggested that maintaining magnesium sulfate infusion for 10 days post-aSAH or until signs of vasospasm disappear might protect against secondary cerebral infarction when markers of vasoconstriction and reduced brain perfusion are present (57, 58). Current evidence does not support the use of magnesium supplementation in clinical practice for aSAH patients beyond magnesium status normalization.

Complications of heart surgery

Atrial arrhythmia (also called atrial fibrillation) is a condition defined as the occurrence of persistent heart rate abnormalities; such arrhythmias often complicate the recovery of patients after cardiac surgery. The use of magnesium in the prophylaxis of postoperative atrial arrhythmia after coronary artery bypass grafting has been evaluated as a sole or adjunctive agent to classical antiarrhythmic molecules (namely, β-blockers and amiodarone) in several prospective, randomized controlled trials. A meta-analysis of 21 intervention studies showed that intravenous magnesium infusions could significantly reduce postoperative atrial arrhythmia in treated compared to untreated patients (59). The results of a more recent meta-analysis of 22 placebo-controlled trials suggested that magnesium may effectively reduce atrial arrhythmia when administered post-operatively, as a bolus, and for more than 24 hours (60). However, another meta-analysis of four trials found that magnesium was no more effective than other antiarrhythmic agents (60). Moreover, the meta-analysis of five randomized controlled trials also suggested that intravenous magnesium added to β-blocker treatment did not decrease the risk of atrial arrhythmia compared to β-blocker alone and was associated with more adverse effects (bradycardia and hypotension) (61). Presently, high-quality evidence is still lacking to support the use of magnesium in the prophylaxis of post-operative atrial fibrillation and other arrhythmias in patients with contraindications to first-line antiarrhythmic agents (60).

Diabetes mellitus

Public health concerns regarding the epidemics of obesity and type 2 diabetes mellitus and the prominent role of magnesium in glucose metabolism have led scientists to investigate the relationship between magnesium intake and type 2 diabetes mellitus. A prospective cohort study that followed more than 25,000 individuals, 35 to 65 years of age, for seven years found no difference in incidence of type 2 diabetes mellitus when comparing the highest (377 mg/day) quintile of magnesium intake to the lowest quintile (268 mg/day) (62). However, inclusion of this study in a meta-analysis of eight cohort studies showed that the risk of type 2 diabetes was inversely correlated with magnesium intake (62). The most recent meta-analysis of 25 prospective cohort studies, including 637,922 individuals and 26,828 new cases of type 2 diabetes mellitus, found that higher magnesium intakes were associated with a 17% lower risk of type 2 diabetes mellitus (63). Several meta-analyses conducted to date reported an 8 to 15% decrease in the risk of developing type 2 diabetes mellitus with each 100 mg-increment in dietary magnesium intake (63-66).

Insulin resistance, characterized by alterations in both insulin secretion by the pancreas and insulin action on target tissues, has been linked to inadequate magnesium status. A cross-sectional analysis of the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) consortium, which included 15 cohorts with a total of 52,684 diabetes-free participants, showed that magnesium intakes were inversely associated with fasting insulin concentrations after multiple adjustments, including various lifestyle factors, body mass index (BMI), caffeine intake, and fiber intake (65). It is thought that pancreatic β-cells, which secrete insulin, could become less responsive to changes in insulin sensitivity in magnesium-deficient subjects (67). A randomized, double-blind, placebo-controlled trial that enrolled 97 healthy adults with significant hypomagnesemia (serum magnesium concentration ≤0.70 mmol/L) showed that daily consumption of 638 mg of magnesium (from a solution of magnesium chloride) for three months improved the function of pancreatic β-cells, resulting in lower fasting glucose and insulin concentrations (68). In a follow-up randomized controlled trial, the administration of 382 mg/day of magnesium for four months to participants (mean age, 42 years) with both hypomagnesemia (serum magnesium concentration <0.74 mmoles/L) and impaired fasting glucose improved serum magnesium concentrations, as well as fasting and post-load glucose concentrations (69). Other metabolic markers, including serum triglycerides, HDL-cholesterol, and a measure of insulin resistance, also improved in magnesium- versus placebo-treated individuals (69). Additionally, similar metabolic improvements have been reported following the supplementation of magnesium (382 mg/day for four months) to participants who were both hypomagnesemic and lean yet metabolically obese (i.e., with metabolic disorders usually associated with obesity) (70). In another study, supplementation with 365 mg/day of magnesium (from magnesium aspartate hydrochloride) for six months reduced insulin resistance in 27 overweight individuals with normal values of serum and intracellular magnesium (71). This latter study suggests that magnesium might have additional effects on glucose tolerance and insulin sensitivity that go beyond the normalization of serum magnesium concentrations in hypomagnesemic individuals.

Osteoporosis

Although decreased bone mineral density (BMD) is the primary feature of osteoporosis, other osteoporotic changes in the collagenous matrix and mineral composition of bone may result in bones that are brittle and more susceptible to fracture (72). Around 60% of total body magnesium is stored in the skeleton and is known to influence both bone matrix and bone mineral metabolism. Magnesium at the surface of bones is also available for dynamic exchange with blood (73). As the magnesium content of bone mineral decreases, hydroxyapatite crystals of bone may become larger and more brittle. Some studies have found lower magnesium content and larger hydroxyapatite crystals in bones of women with osteoporosis compared to disease-free women (74). Inadequate serum magnesium concentrations are known to result in low serum calcium concentrations, resistance to parathyroid hormone (PTH) action, and resistance to some of the effects of vitamin D (calcitriol), all of which can lead to increased bone loss (see the articles on Vitamin D and Calcium). Lower serum magnesium concentrations may not be unusual in postmenopausal women with osteoporosis (75), and hypomagnesemia has been reported as an adverse effect of using the prescription drug teriparatide (Forteo) in the treatment of osteoporosis (76).

Higher dietary magnesium intakes have been associated with increased site-specific (77) and total-body BMD (78) in observational studies, including studies of older adults. More recently, a large cohort study conducted in almost two-thirds of the Norwegian population found the level of magnesium in drinking water to be inversely associated with the risk of hip fracture (79). In the Women's Health Initiative study, data analysis from 4,778 participants (mean age, 63 years) followed for about seven years showed that higher magnesium intakes were associated with higher hip and whole-body BMD but not with reduced hip or total fractures (80). Moreover, the highest versus lowest quintile of total magnesium intakes was associated with a 23% increased risk of lower arm and wrist fractures (80). In a case-cohort study nested within the European Prospective Investigation into Cancer and Nutrition (EPIC)-Norfolk study, which included 5,319 individuals, total magnesium and potassium intakes were found to be inversely associated with heel bone (calcaneus) broadband ultrasound attenuation (BUA) measurements — which are predictive of the risk of incidental fracture — and with the risk of hip fractures (81).

Few studies have addressed the effect of magnesium supplementation on BMD or osteoporosis in humans. In a small group of postmenopausal women with osteoporosis, magnesium supplementation of 750 mg/day for six months followed by 250 mg/day for 18 more months resulted in increased BMD at the wrist after one year, with no further increase after two years of supplementation (82). A study in postmenopausal women who were taking estrogen replacement therapy and a multivitamin supplement found that supplementation with an additional 400 mg/day of magnesium and 600 mg/day of calcium resulted in increased BMD at the heel compared to postmenopausal women receiving estrogen replacement therapy only (83). A more recent randomized controlled study conducted in 20 postmenopausal women with osteoporosis suggested that high-dose supplementation with magnesium citrate (1,830 mg/day) for one month could reduce the rapid rate of bone loss that characterizes osteoporosis (84). Evidence is not yet sufficient to suggest that supplemental magnesium in excess of the RDA could be effective in the prevention of osteoporosis unless normalization of serum magnesium concentration is required (85).

Sarcopenia

Sarcopenia is a condition characterized by a loss of skeletal muscle mass that increases frailty and risk of falls in older adults (86). Several cross-sectional studies have reported a positive association between dietary magnesium intakes and proxy measures of skeletal muscle mass in middle-age and older adults (87-90). A 2014 randomized controlled study in 139 physically active and healthy older women (mean age, 71.5 years) found little-to-no impact of magnesium supplementation (900 mg/day of magnesium oxide) for 12 weeks on body composition and muscle strength, yet the Short Physical Performance Battery [SPPB] test score — a composite indicator of physical function — improved (91). More research is needed to examine further the effect of magnesium supplementation on body composition, muscle strength, and physical performance in older adults, whether physically active or sedentary, and with normal or inadequate magnesium status.

Disease Treatment

The use of pharmacologic doses of magnesium to treat specific disorders is discussed below. Although many of the cited studies utilized supplemental magnesium at doses considerably higher than the tolerable upper intake level (UL), which is 350 mg/day set by the Food and Nutrition Board (see Safety), it is important to note that these studies were all conducted under medical supervision. Because of the potential side effects of high doses of magnesium, especially in the presence of impaired kidney function, any disease treatment trial using oral magnesium doses higher than the UL should be conducted under medical supervision. Moreover, intravenous magnesium has been used in the management of several conditions.

Pregnancy complications

Preeclampsia and eclampsia

Preeclampsia and eclampsia are hypertensive disorders of pregnancy that may occur at any time after 20 weeks' gestation and persist up to six weeks following birth. Preeclampsia (sometimes called toxemia of pregnancy) affects approximately 4% of pregnant women in the US (92). Preeclampsia is defined as the presence of elevated blood pressure (hypertension), protein in the urine, and severe swelling (edema) during pregnancy (93). Eclampsia occurs with the addition of seizures to the triad of preeclamptic symptoms and is a significant cause of perinatal and maternal mortality (93, 94). Although cases of preeclampsia are at high risk of developing eclampsia, one-quarter of eclamptic women do not initially exhibit preeclamptic symptoms (95).

Although lower magnesium concentrations have been reported in the blood and brain of women with preeclampsia than in healthy pregnant women, there is no evidence that magnesium imbalance may cause adverse pregnancy events. A 2014 meta-analysis of 10 randomized controlled trials found no effect of oral magnesium salt administration during normal and at-risk pregnancies on the risk of preeclampsia, perinatal mortality, and small-for-gestational age infants (96).

For many years, high-dose intravenous magnesium sulfate has been the treatment of choice for preventing eclamptic seizures that may occur in association with severe preeclampsia in pregnancy or during labor (97, 98). A systematic review of seven randomized trials in 1,396 women with eclampsia compared the effect of magnesium sulfate administration with diazepam (a known anticonvulsant) treatment on perinatal outcomes. Risks of recurrent seizures and maternal death were significantly reduced by the magnesium regimen compared to diazepam. Moreover, the use of magnesium for the care of eclamptic women resulted in newborns with higher Apgar scores; there was no significant difference in the risk of preterm birth and perinatal mortality (95). Additional research has confirmed that infusion of magnesium sulfate should always be considered in the management of severe preeclampsia and eclampsia to prevent initial and recurrent seizures (99). Moreover, the World Health Organization (WHO) recommends the use of magnesium sulfate — administered either intramuscularly or intravenously — as first-line treatment for the prevention of eclampsia in women with severe preeclampsia, in preference to other anticonvulsants (100). Further research is needed to evaluate the efficacy of magnesium salt infusion in eclampsia prophylaxis in women with mild preeclampsia (101). In addition, it is unclear whether prolonging magnesium use post-partum in women who presented with severe preeclampsia during pregnancy is necessary to lower the risk of eclampsia after delivery (102).

Perinatal neuroprotection

While intravenous magnesium sulfate is included in the medical care of preeclampsia and eclampsia, the American College of Obstetricians and Gynecologists (ACOG) and the Society for Maternal-Fetal Medicine support its use in two additional situations: specific conditions of short-term prolongation of pregnancy and neuroprotection of the fetus in anticipated premature delivery (103).

Preterm birth, which is defined by the premature delivery of an infant between the 20th and 37th weeks of estimated gestation, is associated with an increased risk of perinatal mortality and both short- and long-term morbidity. The ACOG approves the use of different classes of drugs — known as tocolytics — that are meant to delay delivery for long enough so that antenatal corticoids can be used to accelerate lung maturation in the fetus of women at imminent risk of preterm labor (104). A 2014 meta-analysis of 37 trials found that intravenous infusion of magnesium sulfate was no more efficacious than commonly used tocolytics (e.g., β-adrenergic receptor agonists, calcium channel blockers, prostaglandin inhibitors) in delaying delivery or preventing serious infant outcomes (105). Very limited evidence also suggested that high- versus low-dose magnesium infusion may reduce the length of hospital stays in neonates admitted to intensive care units (106).

The relationship between magnesium sulfate and risk of cerebral damage in premature infants has been assessed in observational studies. A meta-analysis of six case-control and five prospective cohort studies showed that the use of magnesium significantly reduced the risk of cerebral palsy, as well as mortality (107). However, the high degree of heterogeneity among the cohort studies and the fact that corticosteroid exposure (which is known to decrease antenatal mortality) was higher in the cases of children exposed to magnesium compared to controls imply a cautious interpretation of the results. Nonetheless, a meta-analysis of five randomized controlled trials, which included 5,493 women at risk of preterm birth and 6,135 babies, found that magnesium therapy given to mothers delivering before term decreased the risk of cerebral palsy by 32% without causing severe adverse maternal events, but this treatment did not reduce the risk of other neurologic impairments or mortality in early childhood (108). Another meta-analysis conducted on five randomized controlled trials found that intravenous magnesium administration to newborns who suffered from perinatal asphyxia could be beneficial in terms of short-term neurologic outcomes, although there was no effect on mortality (109). Additional trials are needed to evaluate the long-term benefits of magnesium in pediatric care.

Cardiovascular disease

Hypertension

While results from intervention studies have not been entirely consistent (2), the latest review of the data highlighted a therapeutic benefit of magnesium supplements in treating hypertension. A 2012 meta-analysis examined 22 randomized, placebo-controlled trials of magnesium supplementation conducted in 1,173 individuals with either normal blood pressure (normotensive) or hypertension (treated with medication or untreated). Oral supplementation with magnesium (mean dose of 410 mg/day; range of 120 to 973 mg/day) for a median period of 11.3 months significantly reduced systolic blood pressure by 2 to 3 mm Hg and diastolic blood pressure by 3 to 4 mm Hg (110); a greater effect was seen at higher doses (≥370 mg/day). The results of 19 of the 22 trials included in the meta-analysis were previously reviewed together with another 25 intervention studies (111). The systematic examination of these 44 trials suggested a blood pressure-lowering effect associated with supplemental magnesium in hypertensive but not in normotensive individuals.

Magnesium doses required to achieve a decrease in blood pressure appeared to depend on whether participants with high blood pressure were treated with antihypertensive medications, including diuretics. Intervention trials on treated participants showed a reduction in hypertension with magnesium doses from 243 mg/day to 486 mg/day, whereas untreated patients required doses above 486 mg/day to achieve a significant decrease in blood pressure. A more recent meta-analysis of randomized controlled studies with 2,028 participants found that supplemental magnesium at a median dose of 368 mg/day (range: 238-960 mg/day) for a median duration of three months (range: 3 weeks-6 months) increased serum magnesium concentration by 0.05 mmol/L (27 trials) and reduced systolic blood pressure by 2 mm Hg and diastolic blood pressure by 1.78 mm Hg (37 trials) (112). A 2017 meta-analysis restricted to trials in participants with underlying preclinical (insulin resistance or prediabetes) or clinical conditions (type 2 diabetes mellitus or coronary heart disease) found a 4.18 mm Hg reduction in systolic blood pressure and a 2.27 mm Hg reduction in diastolic blood pressure with supplemental doses of magnesium ranging between 365 mg/day and 450 mg/day for one to six months (113).

While oral magnesium supplementation may be helpful in hypertensive individuals who are depleted of magnesium due to chronic diuretic use and/or inadequate dietary intake (7), several dietary factors play a role in hypertension. For example, adherence to the DASH diet — a diet rich in fruit, vegetables, and low-fat dairy and low in saturated and total fats — has been linked to significant reductions in systolic and diastolic blood pressures (114). See the topic page: High Blood Pressure.

Atherosclerosis

Vascular endothelial cells line arterial walls where they are in contact with the blood that flows through the circulatory system. Normally functioning vascular endothelium promotes vasodilation when needed, for example, during exercise, and inhibits the formation of blood clots. Conversely, endothelial dysfunction results in widespread vasoconstriction and coagulation abnormalities. In cardiovascular disease, chronic inflammation is associated with the formation of atherosclerotic plaques in arteries. Atherosclerosis impairs normal endothelial function, increasing the risk of vasoconstriction and clot formation, which may lead to heart attack or stroke (reviewed in 115). A recent systematic review identified six randomized controlled trials that examined the effect of pharmacologic doses of oral magnesium on vascular endothelial function (116). Three out of six trials, which included individuals with coronary artery disease (117), diabetes mellitus (118), or hypertension (119), reported an improvement in flow-mediated dilation (FMD) with supplemental magnesium compared to control. In other words, the normal dilation response of the brachial (arm) artery to increased blood flow was improved. In contrast, there was no evidence of an effect of magnesium supplementation on FMD in three trials conducted in hemodialysis patients (120) or healthy participants with normal (121) or high body mass index (BMI) (122). A pooled analysis of the six trials in 262 participants found that supplementation with 107 to 730 mg/day of magnesium for one to six months resulted in an overall improvement of FMD, regardless of the health status or baseline magnesium concentrations of participants (116).

The measurement of the thickness of the inner layers of the carotid arteries is sometimes used as a surrogate marker of atherosclerosis (123). Higher serum magnesium concentrations have been associated with reduced carotid intima-media thickness (CIMT) in all women and in Caucasian men participating in the Atherosclerosis Risk in Communities (ARIC) study (124). A meta-analysis of four small (145 participants in total) and heterogeneous intervention studies found no effect of magnesium supplementation (98.6 to 368 mg/day for 2 to 6 months) on CIMT (116).

Survival after myocardial infarction

Results from several randomized, placebo-controlled trials have suggested that an intravenous magnesium administered early after a suspected myocardial infarction could decrease the risk of death. The most influential study was a randomized, placebo-controlled trial in 2,316 patients that found a significant reduction in mortality in the group of patients given intravenous magnesium sulfate within 24 hours of suspected myocardial infarction (7.8% all-cause mortality in the experimental group vs. 10.3% all-cause mortality in the placebo group) (125). Follow-up from one to five years after treatment revealed that the mortality from cardiovascular disease was 21% lower in the magnesium-treated group (126). However, a larger placebo-controlled trial in more than 58,000 patients found no significant reduction in five-week mortality in patients treated with intravenous magnesium sulfate within 24 hours of suspected myocardial infarction, resulting in controversy regarding the efficacy of this treatment (127). A US survey of the treatment of more than 173,000 individuals with acute myocardial infarction found that only 5% were given intravenous magnesium in the first 24 hours post-infarction and that mortality was higher in this group compared to the group of patients not treated with magnesium (128). A 2007 systematic review of 26 clinical trials, including 73,363 participants, concluded that intravenous magnesium administration does not appear to reduce post-myocardial infarction mortality and thus should not be utilized as a treatment (129). Thus, the use of intravenous magnesium sulfate in the therapy of acute myocardial infarction remains controversial.

Diabetes mellitus

Magnesium depletion has been associated with type 1 (insulin-dependent) and type 2 diabetes mellitus, as well as with gestational diabetes. Low serum concentrations of magnesium (hypomagnesemia) have been reported in 13.5 to 47.7% of individuals with type 2 diabetes mellitus (130). One cause of the depletion may be an increased urinary loss of magnesium caused by an increased urinary excretion of glucose that accompanies poorly controlled diabetes. Magnesium depletion has been shown to increase insulin resistance in a few studies and may adversely affect blood glucose control in diabetes mellitus (see also Diabetes mellitus under Disease Prevention) (131). A small study in nine individuals with type 2 diabetes mellitus reported that supplemental magnesium (300 mg/day for 30 days), in the form of a liquid, magnesium-containing salt solution, improved fasting insulin but not fasting glucose concentrations (132). One randomized, double-blind, placebo-controlled study in 63 individuals with type 2 diabetes mellitus and hypomagnesemia found that those taking an oral magnesium chloride solution (638 mg/day of elemental magnesium) for 16 weeks had improved measures of insulin sensitivity and glycemic control compared to those taking a placebo (133). The most recent meta-analysis of nine randomized, double-blind, controlled trials concluded that oral supplemental magnesium lowered fasting plasma glucose concentrations in individuals with diabetes (134). However, magnesium supplementation did not improve other markers of glucose homeostasis, such as glycated hemoglobin (HbA1c) concentration, fasting and post-glucose load insulin concentrations, and measures of insulin resistance (134). Another meta-analysis of trials that included participants either at-risk of diabetes mellitus or with diabetes mellitus suggested that evidence to support a benefit of magnesium supplementation on measures of insulin resistance was stronger in subjects who were magnesium deficient than in those with normal serum concentrations of magnesium (135). Correcting existing magnesium deficiencies may improve glucose metabolism and insulin sensitivity in subjects with diabetes, but it remains uncertain whether magnesium supplementation can have any therapeutic benefit in patients with adequate magnesium status.

Asthma

The occurrence of hypomagnesemia may be greater in patients with asthma than in individuals without asthma (136). Several clinical trials have examined the effect of intravenous magnesium infusions on acute asthmatic attacks in children or adults who did not respond to initial treatment in the emergency room. Indeed, magnesium can promote bronchodilation in subjects with asthma by interfering with mechanisms like the activation of N-methyl D-aspartate (NMDA) receptors that trigger bronchoconstriction through facilitating calcium influx in airway smooth muscle cells (137). In a meta-analysis of six (quasi) randomized controlled trials in 325 children with acute asthma treated with a short-acting β_2-adrenergic receptor agonist (e.g., salbutamol) and systemic steroids, intravenous magnesium sulfate treatment improved measurements of the respiratory function and reduced the risk of hospital admission by 30% compared to control (138). Another meta-analysis of randomized controlled trials primarily conducted in adults with asthma exacerbations indicated that single infusions of 1.2 to 2 g of magnesium sulfate over 15 to 30 minutes could reduce the risk of hospital admission and improve lung function after initial treatments failed (i.e., oxygen, short-acting β_2 agonist, and steroids) (139).

The use of nebulized, inhaled magnesium for treating asthma has also been investigated. A recent systematic review of 25 randomized controlled trials, including adults, children, or both, found little evidence that inhaled magnesium sulfate alone or along with a β_2-adrenergic receptor agonist and/or a muscarinic anticholinergic (e.g., ipratropium) could improve pulmonary function in patients with acute asthma (140). In addition, oral magnesium supplementation is of no known value in the management of chronic asthma (141-143).

Pain management

The potential analgesic effect of magnesium is attributed in particular to its capacity to block NMDA receptors, which are located in the brain and spinal cord and are involved in pain transduction (144).

Post-operative pain

Several intervention studies have examined the role of magnesium on pain control and analgesic requirement in patients during the immediate post-surgery period.

After cesarean section: Pain management strategies after cesarean section usually involve the injection of an analgesic into either the epidural space (for epidural analgesia) or the subarachnoid space (for spinal [intrathecal] analgesia). A recent meta-analysis of nine randomized controlled trials summarized the evidence regarding the potential use of magnesium sulfate to control or relieve postoperative pain in 827 women who underwent cesarean section (145). All the trials evaluated the effect of a first-line analgesic regimen (i.e., bupivacaine or lidocaine, with or without opioids) with and without the addition of magnesium sulfate. The results suggested that the anesthesia (8 studies) and sensory blockade (6 studies) lasted longer in women who received the additional magnesium sulfate. The use of magnesium sulfate also resulted in lower pain score (3 studies) and in lower postoperative consumption of analgesics (4 studies). Additionally, there was no difference in occurrence of side effects between regimens (145). A recent randomized controlled trial in 60 healthy women undergoing elective cesarean section confirmed that the addition of magnesium sulfate to a bupivacaine/opioid regimen increased the duration of spinal anesthesia and lowered the pain level, yet did not improve the potency of bupivacaine (146). In another study in women with mild preeclampsia who received an epidural injection of ropivacaine after cesarean section, spinal infusion of magnesium sulfate increased the duration of sensory and motor blockade, as well as the time before patients requested an analgesic, compared to midazolam (147).

After a variety of other surgeries: The efficacy of intravenous magnesium has also been examined for local, regional, or systemic pain control following a range of different surgeries. A review of four small randomized controlled studies suggested that, when added to local analgesics, magnesium infusion to patients undergoing tonsillectomy might decrease pain and incidence of laryngospasm, extend the time to first post-operative analgesic requirement, and reduce the number of post-operative analgesic requests (148). Similar observations were reported in two additional meta-analyses, yet there was discrepancy regarding the ability of magnesium to alleviate pain (149, 150). Indeed, the review of eight trials by Xie et al. (150), of which only two scored pain using the same scale, showed no pain reduction with magnesium compared to control. Finally, both meta-analyses reported no reduction in risk of post-operative nausea and vomiting with intravenous magnesium administration (148, 150). A 2018 meta-analysis of four randomized controlled trials in 263 patients also suggested that magnesium sulfate infusion may help reduce pain scores at 2 and 8 hours (but not 24 hours) after laparoscopic cholecystectomy (151). Recent studies have examined the use of magnesium sulfate for pain control after other surgeries, including hysterectomy (152, 153), spinal surgery (154, 155), or during endoscopic sinus (156) or cochlear implantation (157) surgery. Despite conflicting results or reports of limited benefits of magnesium, further research is needed before any conclusions can be drawn.

Neuropathic pain

The effect of magnesium on neuropathic pain has been examined in some clinical studies. The intravenous administration of magnesium sulfate was found to partially or completely alleviate pain in patients with postherpetic neuralgia, a type of neuropathic pain caused by herpes zoster infection (shingles) (158, 159). In a more recent randomized controlled trial in 45 patients with either postherpetic neuralgia or neuropathic pain of traumatic or surgical origin, oral supplementation of magnesium failed to improve measures of pain and quality of life compared to a placebo (160). Another trial is underway to examine the impact of intravenous magnesium with ketamine on neuropathic pain (161).

Migraine headaches

Lower intracellular magnesium concentrations (in both red blood cells and white blood cells) have been reported in individuals who suffer from recurrent migraine headaches compared to migraine-free individuals (162). Additionally, the incidence of hypomagnesemia also appeared to be greater in women who experience migraines with menstruation compared to women without menstrual migraines (163).

A few intervention studies have examined whether an increase in intracellular magnesium concentration with supplemental (oral) magnesium could help decrease the frequency and severity of migraine headaches in affected individuals. Two early placebo-controlled trials demonstrated modest decreases in the frequency of migraine headaches after supplementation with 600 mg/day of magnesium (162, 164). Another placebo-controlled trial in 86 children with frequent migraine headaches found that oral magnesium oxide (9 mg/kg body weight/day) reduced headache frequency over the 16-week intervention (165). However, there was no reduction in the frequency of migraine headaches with 485 mg/day of magnesium in another placebo-controlled study conducted in 69 adults suffering migraine attacks (166). The efficiency of magnesium absorption varies with the type of oral magnesium complex, and this might explain the conflicting results. Although no serious adverse effects were noted during these migraine headache trials, 19 to 40% of individuals taking the magnesium supplements have reported diarrhea and gastric irritation.

The efficacy of magnesium infusions was also investigated in a randomized, single-blind, placebo-controlled, cross-over trial of 30 patients with migraine headaches (167). The administration of 1 gram of intravenous magnesium sulfate ended the attacks, abolished associated symptoms, and prevented recurrence within 24 hours in nearly 90% of the subjects. While this promising result was confirmed in another trial (168), two additional randomized, placebo-controlled studies found that magnesium sulfate was less effective than other molecules (e.g., metoclopramide) in treating migraines (169, 170). The most recent meta-analysis of five randomized, double-blind, controlled trials reported no beneficial effect of magnesium infusion for migraine in adults (171). Another two more recent intervention studies suggested that magnesium sulfate infusion could be more effective and faster than dexamethasone/metoclopramide (172) or caffeine citrate (173) to relieve pain in patients with acute migraine.

The efficacy of magnesium should be examined in larger studies that consider the magnesium status of migraine sufferers (174).

Critical injury or illness

Hypomagnesemia is not uncommon in patients admitted to intensive care units (ICU). Two recent meta-analyses of prospective and retrospective cohort studies reported serum magnesium concentrations ≤0.75 mmol/L in ICU patients at admission or within 24 hours following admission to be associated with a greater need for mechanical ventilation, longer ICU stay, and higher risk of hospital mortality (175, 176). A pooled analysis of three studies also suggested a higher risk of sepsis in ICU patients with hypomagnesemia (175). A recent prospective study conducted in patients admitted with severe head injury found better neurological outcomes after six months in those who presented with normal serum magnesium concentrations at admission compared to those with hypomagnesemia (serum magnesium concentrations <0.65 mmol/L) (177). However, evidence is currently unavailable to suggest that magnesium administration could improve outcomes in critically ill or severely injured patients (178).

Sources

Food sources

The analysis of US national nutrition survey data (NHANES 2003-2006) showed an average magnesium intake in adults (ages ≥19 years) of 278 mg/day when only unfortified food sources were considered (179). Considering all sources of magnesium intakes (i.e., unfortified and fortified food and supplements), the average intake in adults was estimated to be around 330 mg/day — a value close to the estimated average requirements (EAR) for magnesium — suggesting that about one-half of the adult population may be at risk of magnesium inadequacy (179). Yet, the long-term consequences of inadequate dietary intakes remain unclear (1).

Since magnesium is part of chlorophyll, the green pigment in plants, green leafy vegetables are good sources of magnesium. Unrefined grains (whole grains) and nuts also have high magnesium content. Meats and milk have an intermediate content of magnesium, while refined foods generally have the lowest. Water is a variable source of intake; harder water usually has a higher concentration of magnesium salts (2). Some foods that are relatively rich in magnesium are listed in **Table 2**, along with their magnesium content in milligrams (mg). For more information on the nutrient content of foods, search USDA's FoodData Central.

Table 2. Some Food Sources of Magnesium

Food	Serving	Magnesium (mg)
Brazil nuts	1 ounce (6 kernels)	107
Cereal, oat bran	½ cup dry	96
Brown rice, medium-grain, cooked	1 cup	86
Cashews	1 ounce (16 kernels)	83
Fish, mackerel, cooked	3 ounces	82
Spinach, frozen, chopped, cooked	½ cup	78
Almonds	1 ounce (23 kernels)	77
Swiss chard, chopped, cooked	½ cup	75
Lima beans, large, immature seeds, cooked	½ cup	63
Cereal, shredded wheat	2 biscuits	61
Avocado	1 fruit	58
Cereal, all bran (whole wheat)	½ cup, dry	57
Peanuts	1 ounce (28 peanuts)	48
Molasses, blackstrap	1 tablespoon	48
Hazelnuts	1 ounce (21 kernels)	46
Chickpeas, mature seeds, cooked	½ cup	39
Milk, 1% fat	8 fluid ounces	39
Banana	1 medium	32

Supplements

Magnesium supplements are available as magnesium oxide, magnesium hydroxide, magnesium gluconate, magnesium chloride, and magnesium citrate salts, as well as a number of amino acid chelates like magnesium aspartate. Magnesium hydroxide, oxide, or trisilicate salts are used as antacids to mitigate gastric hyperacidity and symptoms of gastroesophageal reflux disease (180).

Safety

Toxicity

Adverse effects have not been identified from magnesium occurring naturally in food. However, adverse effects from excessive magnesium have been observed with intakes of various magnesium salts (i.e., supplemental magnesium) (6). The initial symptom of excess magnesium supplementation is diarrhea — a well-known side effect of magnesium that is used therapeutically as a laxative. Individuals with impaired kidney function are at higher risk for adverse effects of magnesium supplementation, and symptoms of magnesium toxicity have occurred in people with impaired kidney function taking moderate doses of magnesium-containing laxatives or antacids. Elevated serum concentrations of magnesium (hypermagnesemia) may result in a fall in blood pressure (hypotension). Some of the later effects of magnesium toxicity, such as lethargy, confusion, disturbances in normal cardiac rhythm, and deterioration of kidney function, are related to severe hypotension. As hypermagnesemia progresses, muscle weakness and difficulty breathing may occur. Severe hypermagnesemia may result in cardiac arrest (2, 3). The Food and Nutrition Board (FNB) of the US Institute of Medicine set the tolerable upper intake level (UL) for magnesium at 350 mg/day; this UL represents the highest level of daily supplemental magnesium intake likely to pose no risk of diarrhea or gastrointestinal disturbance in almost all individuals. The FNB cautions that individuals with renal impairment are at higher risk for adverse effects from excess supplemental magnesium intake. However, the FNB also notes that there are some conditions that may warrant higher doses of magnesium under medical supervision (2).

Table 3. Tolerable Upper Intake Level (UL) for Supplemental Magnesium

Age Group	UL (mg/day)
Infants 0-12 months	Not possible to establish*
Children 1-3 years	65
Children 4-8 years	110
Children 9-13 years	350
Adolescents 14-18 years	350
Adults 19 years and older	350
*Source of intake should be from food and formula only.	

Drug interactions

Magnesium interferes with the absorption of digoxin (a heart medication), nitrofurantoin (an antibiotic), and certain anti-malarial drugs, which could potentially reduce drug efficacy. Bisphosphonates (e.g., alendronate, etidronate), which are drugs used to treat osteoporosis, and magnesium should be taken two hours apart so that the absorption of the bisphosphonates is not inhibited (181, 182). Magnesium has also been found to reduce the efficacy of chlorpromazine (a tranquilizer), penicillamine, oral anticoagulants, and the quinolone and tetracycline classes of antibiotics (181, 182). Intravenous magnesium might inhibit calcium entry into smooth muscle cells and lead to hypotension and muscular weakness if administered with calcium channel blockers (e.g., nifedipin, nicardipin) (182). Because intravenous magnesium has increased the effects of certain muscle-relaxing medications used during anesthesia, it is advisable to let medical staff know if you are taking oral magnesium supplements, laxatives, or antacids prior to surgical procedures. Moreover, long-term use (three months or longer) of proton-pump inhibitors (drugs used to reduce the amount of stomach acid) may increase the risk of hypomagnesemia (183, 184). High doses of furosemide (Lasix) and some thiazide diuretics (e.g., hydrochlorothiazide), if taken for extended periods, may interfere with magnesium reabsorption in the kidneys and result in magnesium depletion (182). Many other medications may also result in renal magnesium loss (3).

Linus Pauling Institute Recommendation

The Linus Pauling Institute supports the latest RDA for magnesium intake (400 to 420 mg/day for men and 310 to 320 mg/day for women). Despite magnesium being plentiful in foods, it is considered a shortfall nutrient (see the article on Micronutrient Inadequacies in the US Population). Following the Linus Pauling Institute recommendation to take a daily multivitamin/mineral supplement might ensure an intake of at least 100 mg/day of magnesium. Few multivitamin/mineral supplements contain more than 100 mg of magnesium due to its bulk. Eating a varied diet that provides green vegetables, whole grains, and nuts daily should provide the rest of an individual's magnesium requirement.

Older adults (>50 years)

Older adults are less likely than younger adults to consume enough magnesium to meet their needs and should therefore take care to eat magnesium-rich foods in addition to taking a multivitamin/mineral supplement daily (see the article on Micronutrient Inadequacies: Subpopulations at Risk). Since older adults are also more likely to have impaired kidney function, they should avoid taking more than 350 mg/day of supplemental magnesium without medical consultation (see Safety).

Español

Manganese is a mineral element that is both nutritionally essential and potentially toxic. The derivation of its name from the Greek word for magic remains appropriate, because scientists are still working to understand the diverse effects of manganese deficiency and manganese toxicity in living organisms (1).

Function

Manganese (Mn) plays an important role in a number of physiologic processes as a constituent of multiple enzymes and an activator of other enzymes (2).

Antioxidant function

Manganese superoxide dismutase (MnSOD) is the principal antioxidant enzyme in the mitochondria. Because mitochondria consume over 90% of the oxygen used by cells, they are especially vulnerable to oxidative stress. The superoxide radical is one of the reactive oxygen species produced in mitochondria during ATP synthesis. MnSOD catalyzes the conversion of superoxide radicals to hydrogen peroxide, which can be reduced to water by other antioxidant enzymes (3).

Metabolism

A number of manganese-activated enzymes play important roles in the metabolism of carbohydrates, amino acids, and cholesterol (4). Pyruvate carboxylase, a manganese-containing enzyme, and phosphoenolpyruvate carboxykinase (PEPCK), a manganese-activated enzyme, are critical in gluconeogenesis — the production of glucose from non-carbohydrate precursors. Arginase, another manganese-containing enzyme, is required by the liver for the urea cycle, a process that detoxifies ammonia generated during amino acid metabolism (3). In the brain, the manganese-activated enzyme, glutamine synthetase, converts the amino acid glutamate to glutamine. Glutamate is an excitotoxic neurotransmitter and a precursor to an inhibitory neurotransmitter, γ-aminobutyric acid (GABA) (5, 6).

Bone and cartilage formation

Manganese deficiency results in abnormal skeletal development in a number of animal species. Manganese is the preferred cofactor of enzymes called glycosyltransferases; these enzymes are required for the synthesis of proteoglycans that are needed for the formation of healthy cartilage and bone (7).

Wound healing

Wound healing is a complex process that requires increased production of collagen. Manganese is required for the activation of prolidase, an enzyme that functions to provide the amino acid, proline, for collagen formation in human skin cells (8). A genetic disorder known as prolidase deficiency results in abnormal wound healing among other problems and is characterized by abnormal manganese metabolism (7). Glycosaminoglycan synthesis, which requires manganese-activated glycosyltransferases, may also play an important role in wound healing (9).

Nutrient interactions

Iron

Iron and manganese share common absorption and transport proteins, including the divalent metal transporter 1, the lactoferrin receptor, transferrin, and ferroportin (reviewed in 10). Absorption of manganese from a meal decreases as the meal's iron content increases (7). Iron supplementation (60 milligrams [mg]/day for four months) has been associated with decreased blood manganese concentrations and decreased MnSOD activity in leukocytes, indicating a reduction in manganese nutritional status (11).

Additionally, an individual's iron status can affect manganese bioavailability. Intestinal absorption of manganese is increased during iron deficiency and decreased when iron stores are elevated (i.e., high ferritin concentrations) (12). Small studies have found increased blood concentrations of manganese in iron-deficient infants (13) and children (14), and a national survey of adults residing in South Korea found men and women with low ferritin levels had higher blood concentrations of manganese compared to those with normal ferritin levels (15). In this analysis, anemia was associated with higher blood concentrations of manganese in women but not in men (15). Men generally absorb less manganese than women, which may be related to the fact that men usually have higher iron stores than women (16). Iron deficiency has also been shown to increase the risk of manganese accumulation in the brain (17).

Magnesium

Supplemental magnesium (200 mg/day) has been shown to slightly decrease manganese bioavailability in healthy adults, either by decreasing manganese absorption or by increasing its excretion (18).

Calcium

In one set of studies, supplemental calcium (500 mg/day) slightly decreased manganese bioavailability in healthy adults. As a source of calcium, milk had the least effect, while calcium carbonate and calcium phosphate had the greatest effect (18). Several other studies have found minimal effects of supplemental calcium on manganese metabolism (19).

Regulation

Although manganese is a nutritionally essential mineral, it is potentially toxic; thus, it is important for the body to tightly regulate manganese homeostasis. While the exact mechanisms that govern manganese homeostasis are not completely understood, systemic regulation is achieved through intestinal control of manganese absorption and hepatic excretion of manganese into bile (20). At the cellular level, influx of manganese into cells is regulated by several different transport proteins, including the transferrin receptor, the divalent metal transporter 1 (DMT 1), zinc-interacting proteins 8 and 14 (ZIP8 and ZIP14), as well as others (reviewed in 21). Efflux of manganese from cells is accomplished by various transporters, including SLC30A10; the sodium-calcium exchanger; and the iron transporter, ferroportin (reviewed in 22). Moreover, subcellular organelles (i.e., the nucleus, mitochondria, Golgi apparatus, lysosome, endosome) utilize various transporters for manganese trafficking within the cell, but the exact mechanisms of regulation are not fully understood (21).

Deficiency

Manganese deficiency has been observed in a number of animal species, but manganese deficiency is not a concern in humans. Signs of manganese deficiency vary among animal species and may include impaired growth, impaired reproductive function, skeletal abnormalities, impaired glucose tolerance, and altered carbohydrate and lipid metabolism. In humans, demonstration of a manganese deficiency syndrome has been less clear (2, 7). A child on long-term total parenteral nutrition (TPN) lacking manganese developed bone demineralization and impaired growth that were corrected by manganese supplementation (23). Young men who were fed a low-manganese diet developed decreased serum cholesterol concentrations and a transient skin rash (24). Blood concentrations of calcium, phosphorus, and alkaline phosphatase were also elevated, which may indicate increased bone remodeling as a consequence of insufficient dietary manganese. Young women fed a manganese-poor diet developed mildly abnormal glucose tolerance in response to an intravenous (IV) infusion of glucose (19). Overall, manganese deficiency is quite rare, and there is more concern for toxicity related to manganese overexposure (see Safety).

The Adequate Intake (AI)

Because there was insufficient information on manganese requirements to set a Recommended Dietary Allowance (RDA), the Food and Nutrition Board (FNB) of the Institute of Medicine (now the National Academy of Medicine) set an adequate intake (AI). Since overt manganese deficiency has not been documented in humans eating natural diets, the FNB based the AI on average dietary intakes of manganese determined by the Total Diet Study — an annual survey of the mineral content of representative American diets (4). AI values for manganese are listed in **Table 1** in milligrams (mg)/day by age and gender. Manganese requirements are increased in pregnancy and lactation (4).

Table 1. Adequate Intake (AI) for Manganese

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	0.003	0.003
Infants	7-12 months	0.6	0.6
Children	1-3 years	1.2	1.2
Children	4-8 years	1.5	1.5
Children	9-13 years	1.9	1.6
Adolescents	14-18 years	2.2	1.6
Adults	19 years and older	2.3	1.8
Pregnancy	all ages	-	2.0
Breast-feeding	all ages	-	2.6

Disease Prevention

Low dietary manganese intake or low levels of manganese in blood or tissue have been associated with various chronic diseases. Although manganese insufficiency is not currently thought to cause the diseases discussed below, more research may be warranted to determine whether suboptimal manganese nutritional status contributes to certain disease processes.

Osteoporosis

Early studies found women with osteoporosis had decreased plasma or serum concentrations of manganese and an enhanced plasma response to an oral dose of manganese (25, 26), suggesting they may have lower manganese status than women without osteoporosis. However, more recent studies in postmenopausal women have reported conflicting results, with one study finding lower blood manganese concentrations among women with osteoporosis compared to those without osteoporosis (27) and another finding no differences (28). A study in healthy postmenopausal women found that a supplement containing manganese (5 mg/day), copper (2.5 mg/day), and zinc (15 mg/day) in combination with a calcium supplement (1,000 mg/day) was more effective than the calcium supplement alone in preventing spinal bone loss over a two-year period (29). However, the presence of other trace elements in the supplement makes it impossible to determine whether manganese supplementation was the beneficial agent for maintaining bone mineral density.

Diabetes mellitus

In animal models, manganese deficiency results in impaired insulin secretion and glucose intolerance similar to diabetes mellitus (30); however, results of human studies on manganese and type 2 diabetes have been somewhat conflicting. Manganese intake was inversely associated with type 2 diabetes in 71,270 French women participating in the E3N-EPIC cohort study (31). In an analysis of two prospective cohorts of Chinese adults (ages 20-74 years at baseline), followed for a mean of 4.2 and 5.3 years, higher dietary intakes of manganese were associated with a lower risk of type 2 diabetes; these associations were independent of dietary total antioxidant capacity, a measure of dietary antioxidant intake (32). Most recently, a prospective cohort study of 19,862 adults (ages 40-79 at baseline) participating in the Japan Collaborative Cohort Study, followed for five years, found higher dietary intake of manganese to be associated with a lower risk of type 2 diabetes in women but not in men (33).

While these studies of dietary manganese intake are suggestive of a protective association with type 2 diabetes, studies employing biomarkers of manganese intake – either blood concentrations of manganese or urinary manganese excretion — have reported mixed results. Most studies conducted have been small case-control studies; studies to date have reported blood manganese concentrations in patients with diabetes were higher (34-36), lower (37), or similar (38-40) compared to blood manganese concentrations in controls without diabetes. Additionally, a case-control study that included 3,228 adults in China reported a U-shaped relationship between plasma concentration of manganese and type 2 diabetes, meaning those with low or high blood concentrations had a higher odds of diabetes when compared to those with an intermediate blood concentration of manganese (41). In a cross-sectional analysis of adults participating in the Korean National Health and Nutrition Examination Survey, blood concentrations of manganese were significantly lower among those with diabetes compared to those without diabetes (42). Further, one case-control study found higher urinary manganese excretion in patients with diabetes compared to controls without diabetes (37). Results of case-control studies are more likely to be distorted by bias (i.e., the selection bias with the selection of cases and controls, as well as dietary recall bias) than results of prospective cohort studies.

Moreover, one study of functional manganese status found the activity of the antioxidant enzyme, MnSOD, to be lower in the white blood cells of patients with diabetes than in those without diabetes (43). When given at the same time as an oral glucose challenge, an acute oral dose of 15 mg or 30 mg manganese did not improve glucose tolerance in subjects with diabetes or in controls without diabetes (44).

Although manganese appears to play a role in glucose metabolism, it is not clear whether higher manganese status might improve glucose tolerance and protect against the development of type 2 diabetes mellitus.

Epilepsy (seizure disorders)

Manganese deficient rats are more susceptible to seizures than manganese sufficient rats, and rats that are genetically prone to epilepsy have lower than normal brain and blood manganese concentrations. Certain subgroups of humans with epilepsy reportedly have lower whole blood manganese concentrations than control subjects without epilepsy (45). One study found blood manganese concentrations of individuals with epilepsy of unknown origin were lower than those of individuals whose epilepsy was induced by trauma (e.g., head injury) or disease (46), suggesting a possible genetic relationship between epilepsy and abnormal manganese metabolism. While manganese deficiency does not appear to be a cause of epilepsy in humans, the relationship between manganese metabolism and epilepsy deserves further research (7, 45, 47).

Sources

Food sources

In the US, estimated average intakes of dietary manganese range from 2.1 to 2.3 mg/day for men and 1.6 to 1.8 mg/day for women (4). Surveys have found those adhering to a vegetarian diet have manganese intakes of up to 7.0 mg/day (reviewed in 48). Rich sources of manganese include whole grains, legumes, nuts, leafy vegetables, and teas (49). Foods high in phytic acid, such as beans, seeds, nuts, whole grains, and soy products, or foods high in oxalic acid, such as cabbage, spinach, and sweet potatoes, may slightly inhibit manganese absorption. Although teas are rich sources of manganese, the tannins present in tea may moderately reduce the absorption of manganese (18). Intakes of other minerals, including iron, calcium, and phosphorus, have been found to limit retention of manganese (4). The manganese content of some manganese-rich foods is listed in milligrams (mg) in **Table 2**. For more information on the nutrient content of foods, search USDA's FoodData Central database (50).

Table 2. Some Food Sources of Manganese

Food	Serving	Manganese (mg)
Pineapple, raw	½ cup, chunks	0.77
Pineapple juice	½ cup (4 fl. oz.)	0.63
Pecans	1 ounce (19 halves)	1.28
Almonds	1 ounce (23 whole kernels)	0.62
Peanuts	1 ounce	0.55
Peanut butter, smooth style, no salt	2 tablespoons	0.53
Instant oatmeal (prepared with water)	1 packet	0.99
Raisin bran cereal	1 cup	0.78-3.02
Brown rice, long-grain, cooked	½ cup	0.99
Whole-wheat bread	1 slice	0.70
Pinto beans, cooked	½ cup	0.39
Lima beans, cooked	½ cup	0.49
Navy beans, cooked	½ cup	0.48
Spinach, cooked	½ cup	0.84
Sweet potato, cooked	½ cup, mashed	0.44
Tea (green)	1 cup (8 ounces)	0.41-1.58
Tea (black)	1 cup (8 ounces)	0.18-0.77

Breast milk and infant formulas

Infants are exposed to varying amounts of manganese depending on their source of nutrition. Manganese concentrations in breast milk, cow-based formula, and soy-based formula range from 3 to 10 micrograms/liter (μg/L), 30 to 50 μg/L, and 200 to 300 μg/L, respectively. However, the bioavailability of manganese from breast milk is higher than from infant formulas, and manganese deficiencies in breast-fed infants or toxicities in formula-fed infants have not been reported (20).

Water

Manganese concentrations in drinking water range from 1 to 100 micrograms (μg)/L, but most sources contain less than 10 μg/L (51). The US Environmental Protection Agency (EPA) recommends 0.05 mg (50 μg)/L as the maximum allowable manganese concentration in drinking water (52).

Supplements

Several forms of manganese are found in supplements, including manganese gluconate, manganese sulfate, manganese ascorbate, and amino acid chelates of manganese. Manganese is available as a stand-alone supplement or in combination products (53). Relatively high levels of manganese ascorbate may be found in a bone/joint health product containing chondroitin sulfate and glucosamine hydrochloride (see Safety).

Parenteral nutrition

Manganese may be present in solutions of parenteral nutrition either included as a trace element or as an incidental contaminant (see Intravenous manganese in the Safety section) (54, 55).

Safety

Toxicity

Inherited manganese-overload disorders

Autosomal recessive mutations in the *SLC30A10* gene, which encodes a manganese transporter expressed in the liver and brain, causes a manganese overload syndrome. Such loss-of-function mutations lead to manganese accumulation in certain brain regions and in the liver, causing hypermanganesemia, dystonia parkinsonism, and hepatic dysfunction at an early age (56, 57). Autosomal recessive mutations in the *SLC39A14* gene have also been reported, leading to hypermanganesemia and similar a neurological phenotype, but liver disease is absent with this specific mutation (58). Chelation therapy is important to treat these inherited manganese-overload disorders (59).

Inhaled manganese

Manganese toxicity may result in multiple neurologic problems and is a well-recognized health hazard for people who inhale manganese dust, such as welders, miners, and smelters (1, 4). Unlike ingested manganese, inhaled manganese is transported directly to the brain before it can be metabolized in the liver (60, 61). The symptoms of manganese toxicity generally appear slowly over a period of months to years. In its worst form, manganese toxicity can result in a permanent neurological disorder with symptoms similar to those of Parkinson's disease, including tremors, difficulty walking, and facial muscle spasms. This syndrome, often called manganism, is sometimes preceded by psychiatric symptoms, such as irritability, aggressiveness, and even hallucinations (62, 63). Additionally, environmental or occupational inhalation of manganese can cause an inflammatory response in the lungs (64), with clinical symptoms including cough, acute bronchitis, and decreased lung function (65).

Methylcyclopentadienyl manganese tricarbonyl (MMT)

Methylcyclopentadienyl manganese tricarbonyl (MMT) is a manganese-containing compound used in gasoline as an anti-knock additive. Although it has been used for this purpose in Canada for more than 20 years, uncertainty about adverse health effects from inhaled exhaust emissions kept the US EPA from approving its use in unleaded gasoline. In 1995, a US court decision made MMT available for widespread use in unleaded gasoline (60). A study in Montreal, where MMT had been used for more than 10 years, found airborne manganese levels to be similar to those in areas where MMT was not used (66). Another Canadian study found higher concentrations of respirable manganese in an urban versus a rural area, but average concentrations in both areas were below the safe level set by the US EPA (67). The impact of long-term exposure to low levels of MMT combustion products, however, has not been thoroughly evaluated and will require additional study (68).

A single case of reversible neurotoxicity and seizures following unintentional MMT ingestion has been documented: a 54-year old man accidentally drank an MMT-containing anti-knock agent that he assumed was an energy drink due so similar product labeling (69).

Ingested manganese

Limited evidence suggests that high manganese intakes from drinking water may be associated with neurological symptoms similar to those of Parkinson's disease. Severe neurological symptoms were reported in 25 people who drank water contaminated with manganese — and probably other contaminants — from dry cell batteries for two to three months (70). Water manganese concentrations were found to be 14 mg/L almost two months after symptoms began and may have already been declining (1). A study of older adults in Greece found a high prevalence of neurological symptoms in those exposed to water manganese levels of 1.8 to 2.3 mg/L (71), while a study in Germany found no evidence of increased neurological symptoms in people drinking water with manganese levels ranging from 0.3 to 2.2 mg/L compared to those drinking water containing less than 0.05 mg/L of manganese (72). Manganese in drinking water may be more bioavailable than manganese in food. However, none of the studies measured dietary manganese, so total manganese intake in these cases is unknown. In the US, the EPA recommends 0.05 mg/L as the maximum allowable manganese concentration in drinking water (52), but the World Health Organization does not currently have a health-based limit for manganese in drinking water (73, 74).

Additionally, several cross-sectional studies have associated high levels of manganese in drinking water with cognitive and behavioral deficits in children (reviewed in 75). For example, a cross-sectional study of 362 children (ages 6-13 years) in Canada found children with the highest manganese concentrations in home tap water (median of 216 μg/L) had a 6.2-point lower Full Scale IQ (lower Performance IQ but not Verbal IQ) than those with lowest manganese levels in home tap water (median of 1 μg/L) (76). A cohort study that followed 287 of these children for a mean of 4.4 years found that exposure to higher concentrations of manganese in drinking water was linked to a lower Performance IQ among girls but a higher Performance IQ among boys (77). Additionally, a prospective cohort study among 1,265 children in Bangladesh did not find manganese concentration in drinking water (medians of 0.20 mg/L during pregnancy and 0.34 mg/L at 10 years) to be associated with any measure of cognitive ability (i.e., IQ, verbal comprehension, perceptual reasoning, working memory, processing speed) when assessed at age 10 (78). Yet, this study associated manganese in drinking water with higher risks of conduct problems among boys and low prosocial scores among girls (78). In a population-based cohort study in Denmark that followed 643,401 children, exposure to higher manganese concentrations in drinking water was linked to a heightened risk of one subtype of attention-deficit hyperactive disorder (79). Specifically, exposure to a manganese concentration in drinking water of at least 100 μg/L was associated with a 51% higher risk of the ADHD-Inattentive subtype in girls and a 20% higher risk in boys, in comparison to exposure of <5 μg/L — using these exposure comparisons, a 9% increased risk of ADHD-Overall was observed in girls and no difference found in boys (79).

Only a few adverse effects of manganese intake from supplements have been documented. A single case of manganese toxicity was reported in a person who took large amounts of mineral supplements for years (51), while another case was reported as a result of a person taking a Chinese herbal supplement (62). More recently, Parkinson's disease was reported in a woman taking 100 mg/day of manganese chloride for at least two years, followed by 30 mg/day for two months (80).

Manganese toxicity resulting from food alone has not been reported in humans, even though certain vegetarian diets could provide up to 20 mg/day of manganese (4, 51).

Intravenous manganese

Manganese neurotoxicity has been observed in individuals receiving total parenteral nutrition (TPN), both as a result of excessive manganese in the solution and as an incidental contaminant (54). Neonates are especially vulnerable to manganese-related neurotoxicity (81). Infants receiving manganese-containing TPN can be exposed to manganese concentrations about 100-fold higher than breast-fed infants (20). Because of potential toxicities, some argue against including manganese in parenteral nutrition (82).

Individuals with increased susceptibility to manganese toxicity

- **Chronic liver disease:** Manganese is eliminated from the body mainly in bile. Thus, impaired liver function may lead to decreased manganese excretion. Manganese accumulation in individuals with cirrhosis or liver failure may contribute to neurological problems and Parkinson's disease-like symptoms (1, 53).
- **Infants and children:** Compared to adults, infants and children have higher intestinal absorption of manganese, as well as lower biliary excretion of manganese (83). Thus, infants and children are especially susceptible to any negative, neurotoxic effects of manganese. Indeed, several studies in school-aged children have reported deleterious cognitive and behavioral effects following excessive manganese exposure (76, 84-90). Additional studies have associated higher manganese exposures during pregnancy with cognitive and motor deficits in children under six years of age (reviewed in 75).
- **Iron-deficient populations:** Iron deficiency has been shown to increase the risk of manganese accumulation in the brain (17).
- **Individuals with occupational exposures to airborne manganese**, such as welders, miners, and smelters (reviewed in 21).
- **Abusers of the illicit drug, methcathinone (ephedrone):** Intravenous use of manganese-contaminated methcathinone (i.e., when the drug is synthesized with potassium permanganate as the oxidant) can cause lasting neurological damage and a parkinsonism disorder (91, 92).

Due to the severe implications of manganese neurotoxicity, the Food and Nutrition Board (FNB) of the Institute of Medicine (now the National Academy of Medicine) set very conservative tolerable upper intake levels (UL) for manganese; the ULs are listed in **Table 3** according to age (4).

Table 3. Tolerable Upper Intake Level (UL) for Manganese

Age Group	UL (mg/day)
Infants 0-12 months	Not possible to establish*
Children 1-3 years	2
Children 4-8 years	3
Children 9-13 years	6
Adolescents 14-18 years	9
Adults 19 years and older	11
*Source of intake should be from food and formula only.	

Drug interactions

Magnesium-containing antacids and laxatives and the antibiotic medication, tetracycline, may decrease the absorption of manganese if taken together with manganese-containing foods or supplements (53).

High levels of manganese in supplements marketed for bone/joint health

Two studies have found that supplements containing a combination of glucosamine hydrochloride, chondroitin sulfate, and manganese ascorbate are beneficial in relieving pain due to mild or moderate osteoarthritis of the knee when compared to a placebo (93, 94). The dose of elemental manganese supplied by the supplements was 30 mg/day for eight weeks in one study (94) and 40 mg/day for six months in the other study (93). No adverse effects were reported during either study, and blood manganese concentrations were not measured. Neither study compared the treatment containing manganese ascorbate to a treatment containing glucosamine hydrochloride and chondroitin sulfate without manganese ascorbate, so it is impossible to determine whether the supplement would have resulted in the same benefit without high doses of manganese.

Linus Pauling Institute Recommendation

The adequate intake (AI) for manganese (2.3 mg/day for adult men and 1.8 mg/day for adult women) appears sufficient to prevent deficiency in most individuals. The daily intake of manganese most likely to promote optimum health is not known. Following the Linus Pauling Institute's recommendation to take a multivitamin/mineral supplement containing 100% of the daily values (DV) of most nutrients will generally provide 2.3 mg/day of manganese. Because of the potential for toxicity and the lack of information regarding benefit, manganese supplementation beyond 100% of the DV (2.3 mg/day) is not recommended. There is presently no evidence that the consumption of a manganese-rich plant-based diet results in manganese toxicity.

Older adults (>50 years)

The requirement for manganese is not known to be higher for older adults. However, liver disease is more common in older adults and may increase the risk of manganese toxicity by decreasing the elimination of manganese from the body (see Toxicity). Manganese supplementation beyond 100% of the DV (2.3 mg/day) is not recommended.

Summary

- The molybdenum atom is part of the molybdenum cofactor in the active site of four enzymes in humans: sulfite oxidase, xanthine oxidase, aldehyde oxidase, and mitochondrial amidoxime reducing component. *(More information)*
- Excess molybdenum intake causes fatal copper deficiency diseases in grazing animals. Their rumen is the site of high sulfide generation, and the interaction of molybdenum with sulfur results in the formation of thiomolybdates. Tetrathiomolybdate, a thiomolybdate with four sulfur atoms, can form complexes with copper preventing its absorption and blocking the activity of copper-dependent enzymes. *(More information)*
- In humans, tetrathiomolybdate therapy has been developed for Wilson's disease, a genetic disease in which the accumulation of copper in tissues leads to liver and brain damage. More recently, tetrathiomolybdate use has been explored for the treatment of cancer and inflammatory diseases. *(More information)*
- Mutations in the molybdenum cofactor biosynthetic pathway lead to the combined deficiency of all molybdenum-dependent enzymes. Molybdenum cofactor deficiency Type A is due to mutations in the *MOCS1* gene, while Type B deficiency is caused by mutations in *MOCS2*. Both Type A and Type B deficiencies result in the loss of sulfite oxidase activity, also observed in isolated sulfite oxidase deficiency and characterized by severe neurologic abnormalities in affected patients. *(More information)*
- A new treatment option for molybdenum cofactor deficiency Type A is now available in the US. Intravenous administration of a replacement drug for cyclic pyranopterin monophosphate may help correct the metabolic disorder and prevent neurologic deterioration in patients with Type A deficiency. Patients with Type B deficiency do not lack this molecule and therefore cannot benefit from this treatment. However, one study showed that pyridoxine supplementation in these patients could alleviate suffering by abolishing seizures. *(More information)*
- The molybdenum content of foods depends on the molybdenum content of soils, which can vary considerably. Variation in esophageal cancer incidence worldwide has been linked to the molybdenum content in soils and food. Similar observations have been made in order to identify the factors associated with a population's extended lifespan. *(More information)*

Molybdenum is an essential trace element for virtually all life forms. It functions as a cofactor for a number of enzymes that catalyze important chemical transformations in the global carbon, nitrogen, and sulfur cycles (1). Thus, molybdenum-dependent enzymes are not only required for human health, but also for the health of our ecosystem.

Function

The biological form of the molybdenum atom is an organic molecule known as the molybdenum cofactor (Moco) present in the active site of Moco-containing enzymes (molybdoenzymes) (2). In humans, molybdenum is known to function as a cofactor for four enzymes (3):

In humans, molybdenum is known to function as a cofactor for four enzymes (3).

- **Sulfite oxidase** catalyzes the transformation of sulfite to sulfate, a reaction that is necessary for the metabolism of sulfur-containing amino acids (methionine and cysteine). Recent evidence also indicates a role for sulfite oxidase in the reduction of nitrite to nitric oxide (4).
- **Xanthine oxidase** catalyzes the breakdown of nucleotides (precursors to DNA and RNA) to form uric acid, which contributes to the plasma antioxidant capacity of the blood.
- **Aldehyde oxidase** and xanthine oxidase catalyze hydroxylation reactions that involve a number of different molecules with similar chemical structures. Xanthine oxidase and aldehyde oxidase also play a role in the metabolism of drugs and toxins (5).
- **Mitochondrial amidoxime reducing component (mARC)** was described fairly recently (6), and its precise function is still under investigation. Initial studies showed that mARC forms a three-component enzyme system with cytochrome *b*5 and NADH/cytochrome *b*5 reductase that catalyzes the detoxification of mutagenic *N*-hydroxylated bases (7). mARC reduces various *N*-hydroxylated compounds and plays an important role in prodrug metabolism (8, 9). Moreover, recent studies have found a separate function of this enzyme system: the reduction of nitrite to nitric oxide (10). Two isoforms of the mARC enzyme are known to exist in humans, mARC1 and mARC2 (11).

Of these enzymes, sulfite oxidase is known to be crucial for human health (12). Hereditary xanthinuria, characterized by a deficiency in xanthine oxidase (Type I) or by a deficiency in both xanthine oxidase and aldehyde oxidase (Type II), can be asymptomatic. However, in less than half of the cases, affected individuals exhibit a range of health issues of variable severity (13, 14).

Nutrient interactions

Copper

An early study reported that molybdenum intakes of 500 μg/day and 1,500 μg/day from sorghum increased urinary copper excretion (2). However, the results of a more recent, well-controlled study indicated that very high dietary molybdenum intakes (up to 1,500 μg/day) did not adversely affect copper nutritional status in eight, healthy young men (15).

Tetrathiomolybdate

Excess dietary molybdenum has been found to result in copper deficiency in grazing animals (ruminants). In the digestive tract of ruminants, the formation of compounds containing sulfur and molybdenum, known as thiomolybdates, prevents the absorption of copper and can cause fatal copper-dependent disorders (16, 17). Tetrathiomolybdate (TM) is a molecule that can form high-affinity complexes with copper, controlling free copper (copper that is not bound to ceruloplasmin), and inhibiting copper chaperones and copper-containing enzymes (18, 19). TM's ability to lower free copper levels is exploited in the treatment of Wilson's disease, a genetic disorder characterized by copper accumulation in tissues responsible for hepatic and neurologic disorders. Neurologic worsening has been linked with toxic levels of free copper in the serum of neurologically presenting patients. TM therapy seems able to stabilize neurologic status and prevent neurologic deterioration in these patients, as opposed to the standard initial treatment of choice (20).

Copper is also a required cofactor for enzymes involved in inflammation and angiogenesis that are known to accelerate cancer progression and metastasis. Copper depletion studies employing TM have been initiated in patients with advanced malignancies with the aim of preventing disease progression or relapse. These pilot trials showed promising results in individuals with metastatic kidney cancer (21), metastatic colorectal cancer (22), and breast cancer with high risk of relapse (23). TM was relatively well-tolerated and stabilized disease or prevented relapse in correlation with copper depletion. TM's efficacy has also been investigated in animal models of inflammatory and immune-related diseases (24, 25), but clinical studies are needed to evaluate whether copper depletion might stabilize diseases and improve survival in humans, as suggested by a trial of TM therapy with patients with biliary cirrhosis (26).

Deficiency

Dietary molybdenum deficiency has never been observed in healthy people (2).

Acquired molybdenum deficiency

The only documented case of acquired molybdenum deficiency occurred in a patient with Crohn's disease on long-term total parenteral nutrition (TPN) without molybdenum added to the TPN solution (27). The patient developed rapid heart and respiratory rates, headaches, and night blindness, and ultimately became comatose. The patient was diagnosed with defects in uric acid production and sulfur amino acid metabolism. The patient's clinical condition improved and the amino acid intolerance disappeared when the TPN solution was discontinued and instead supplemented with molybdenum in the form of ammonium molybdate (300 μg/day) (27).

Inherited molybdenum cofactor deficiency

Because molybdenum functions only in the form of the Moco in humans, any disturbance of Moco metabolism can disrupt the function of all molybdoenzymes. Current understanding of the essentiality of molybdenum in humans is based largely on the study of individuals with very rare inborn metabolic disorders caused by a deficiency in Moco. Moco is synthesized *de novo* by a multistep metabolic pathway involving four genes: *MOCS1*, *MOCS2*, *MOCS3*, and *GPHN* (see **Figure 1** below). To date, more than 60 mutations affecting mostly *MOCS1* and *MOCS2* have been identified (28).

The absence of a functional Moco has a direct impact on the activity of the molybdoenzymes. Metabolic disorders specifically associated with deficiency in sulfite oxidase activity include an accumulation of sulfite, taurine, S-sulfocysteine, and thiosulfate (see **Figure 2** below). This metabolic profile is identical to that observed in isolated sulfite oxidase deficiency (ISOD), an inherited condition caused by mutations in the *SUOX* gene that codes for sulfite oxidase (29). Compared with ISOD, Moco deficiency (MocoD) also affects the xanthine pathway and leads to an accumulation of hypoxanthine and xanthine, and low to undetectable uric acid concentrations in blood (see **Figure 3** below). MocoD and ISOD have been diagnosed in more than 100 individuals worldwide. However the global prevalence of MocoD is likely to be underestimated as a result of a failure to diagnose or to report (28, 30, 31). The incidence of MocoD has been recently estimated at one in 100,000 to 200,000 live births (32).

Both MocoD and ISOD result from recessive traits, meaning that only individuals who inherit two copies of the abnormal gene (one from each parent) develop the disease. Individuals who inherit only one copy of the abnormal gene are known as carriers of the trait but do not exhibit any symptoms. ISOD and MocoD can be diagnosed relatively early in pregnancy (10-14 weeks' gestation) by enzyme activity assays using amniotic cell and chorionic villus sampling and by genetic testing (30, 33). These disorders typically occur in the first days of life, although a few cases of MocoD with late presentation have been described (34-37). The loss of sulfite oxidase activity in ISOD and MocoD leads to severe neurological dysfunction characterized by cerebral atrophy, mental retardation, intractable seizures, and dislocation of ocular lenses. At present, it is not clear whether the neurologic effects are a result of the accumulation of a toxic metabolite, such as sulfite, or inadequate sulfate production. Patients with ISOD and MocoD were also found with elevated excretion of α-amino adipic semialdehyde (α-AASA) (38). α-AASA accumulation is the metabolic signature of a deficiency in α-AASA dehydrogenase observed in patients with pyridoxine-dependent epilepsy. The enzymatic deficiency in these individuals causes an increase in α-AASA and its cyclic form piperideine-6-carboxylate (P6C). P6C can trap pyridoxal-5-phosphate (PLP), the active form of vitamin B_6 (pyridoxine), leading to a deficiency in PLP, which is corrected with supplemental pyridoxine. A decrease in PLP has also been observed in the cerebrospinal fluid from ISOD and MocoD patients (39). It is not clear whether sulfite is responsible for the accumulation of α-AASA and the deficiency in PLP in ISOD and MocoD patients. Nevertheless, pyridoxine and folic acid supplementation in patients with MocoD successfully normalized the PLP level and abolished seizures in two patients with mutations in *MOCS2* (MocoD Type B) (40). Although anti-seizure medications and dietary restriction of sulfur-containing amino acids may be beneficial in some cases (41), there are no treatment options for patients with mutations in the *MOCS2*, *GPHN* (MocoD Type C), or *SUOX* genes. Pyridoxine supplementation is an option being considered to alleviate specific clinical features in patients.

A successful treatment using cyclic pyranopterin monophosphate (cPMP) has been described for patients with mutations in the *MOCS1* gene (i.e., those with MocoD Type A) (42). The *MOCS1* gene controls the initial step in the Moco biosynthetic pathway, catalyzing the conversion of guanosine triphosphate into cPMP. Therefore, patients with mutations in the *MOCS1* gene lack cPMP. Daily administration of cPMP to patients resolved all metabolic abnormalities associated with defective sulfite oxidase and xanthine pathways and prevented further signs of neurologic deterioration (43, 44). Early diagnosis and initiation of treatment are essential to ensure success (44). A prospective cohort study of 16 young infants, followed for five years, found that intravenous cPMP treatment was associated with clinical improvement in most infants with MocoD Type A but not in those with MocoD Type B (42). The US Food and Drug Administration recently approved the cPMP replacement drug, fosdenopterin (brand name: Nulibry), for intravenous treatment of MocoD Type A (45). Since cPMP replacement therapy can only benefit MocoD Type A, additional treatment methods are required. A mouse model for MocoD Type B has been recently developed, which may aid in the development of a therapy for those suffering from the *MOSC2* mutation (46).

The Recommended Dietary Allowance (RDA)

The recommended dietary allowance (RDA) for molybdenum was most recently revised in January 2001 by the Food and Nutrition Board of the Institute of Medicine (now the National Academy of Medicine) (2). It was based on the results of nutritional balance studies conducted in eight, healthy young men under controlled laboratory conditions (47, 48). The RDA values for molybdenum are listed in **Table 1** in micrograms (μg)/day by age and gender. Adequate intake (AI) levels were set for infants based on mean molybdenum intake from human milk, exclusively. The Daily Value (DV), derived from the RDA, is 45 μg/day for individuals 4 years of age or older (49).

Table 1. Recommended Dietary Allowance (RDA) for Molybdenum

Life Stage	Age	Males (μg/day)	Females (μg/day)
Infants	0-6 months	2 (AI)	2 (AI)
Infants	7-12 months	3 (AI)	3 (AI)
Children	1-3 years	17	17
Children	4-8 years	22	22
Children	9-13 years	34	34
Adolescents	14-18 years	43	43
Adults	19 years and older	45	45
Pregnancy	all ages	-	50
Breast-feeding	all ages	-	50

Disease Prevention

Esophageal cancer

Linxian is a small region in northern China where the incidence of cancer of the esophagus and stomach is very high (10 times higher than the average in China and 100 times higher than the average in the US). The soil in this region is low in molybdenum and other mineral elements; therefore, dietary molybdenum intake is also low. Studies conducted in other areas of low and high incidence of esophageal cancer showed that content of molybdenum and zinc in hair and nails is significantly lower in inhabitants of high-risk regions compared to cold spots. Moreover, esophageal cancer patients display reduced content of the trace elements compared to healthy relatives (50, 51).

Increased intake of nitrosamines, which are known carcinogens, may be one of a number of dietary and environmental factors that contributes to the development of esophageal cancer in residents of high-risk regions. Adding ammonium molybdate to the soil may help decrease the risk of esophageal cancer by limiting nitrosamine exposure. It is not clear whether dietary molybdenum supplementation is beneficial in decreasing the risk of esophageal cancer. A placebo-controlled, intervention trial conducted in the Linxian area found that supplementation with molybdenum (30 μg/day) and vitamin C (120 mg/day) for 5.25 years did not decrease the incidence or mortality from esophageal cancer (52-54). The 25-year follow-up of this trial found that co-supplementation with these two micronutrients actually led to small increases in risk of death from gastric cardia cancer and cancer in general, but not death from esophageal cancer (54). However, a subanalysis of this 25-year follow-up revealed that co-supplementation with molybdenum and vitamin C slightly increased risk of mortality from esophageal cancer in those who were 55 years or older when the trial initially began (HR, 1.16; 95% CI: 1.04-1.30) (54).

Longevity

Rugao is a county in Jiangsu province (China) renowned for the longevity of its residents. Extended longevity can hardly be attributed to significant differences in traditions, lifestyles, or dietary habits among the residents, and most longevous people are not related to one another, limiting the possible influence of genetics. However, the county has a large number of different soils whose compositions could affect the distribution of trace elements in water and crops and ultimately be linked with human health and longevity. Significant correlations were found between the ratio of people over 90 years old per 100,000 inhabitants and trace elements, including molybdenum, in soils, drinking water, and rice, which constitute key elements of their natural environment (55). The percentage of long-lived people (>80 years old) in Zhongxiang (Hubei province) was also positively linked to the content of molybdenum in their staple food, rice (56). In these regions, it is likely that combinations of trace elements contribute to optimum health and longevity as opposed to the sole effect of molybdenum.

Sources

Food sources

The Total Diet Study, an annual survey of the mineral content in the typical American diet, indicates that the dietary intake of molybdenum averages 76 μg/day for women and 109 μg/day for men. Thus, usual molybdenum intakes are well above the RDA for molybdenum. Legumes, such as beans, lentils, and peas, are the richest sources of molybdenum. Grain products and nuts are considered good sources, while animal products, fruit, and many vegetables are generally low in molybdenum (2). Because the molybdenum content of plants depends on the soil molybdenum content and other environmental conditions, the molybdenum content of foods can vary considerably (51, 57).

Supplements

Molybdenum in single-nutrient and multiple nutrient supplements is of various forms, including sodium molybdate, ammonium molybdate, molybdenum citrate, molybdenum chloride, and molybdenum glycinate, among others (58).

Parenteral nutrition

Molybdenum may be present in solutions of parenteral nutrition either included as a trace element or as an incidental contaminant (59, 60).

Safety

Toxicity

The toxicity of molybdenum compounds appears to be relatively low in humans. Increased serum concentrations of uric acid and ceruloplasmin (an iron-oxidizing enzyme) have been reported in occupationally exposed workers in a molybdenite roasting plant (61). Gout-like symptoms have also been reported in an Armenian population consuming 10 to 15 milligrams (mg) of molybdenum from food daily (62). In other studies, blood and urinary uric acid concentrations were not elevated by molybdenum intakes up to 1.5 mg/day (2). There has been only one report of acute toxicity related to molybdenum from a dietary supplement: an adult male reportedly consumed a total of 13.5 mg of molybdenum over a period of 18 days (300 to 800 μg/day) and developed acute psychosis with hallucinations, seizures, and other neurologic symptoms (63). However, a controlled study in four, healthy young men found that molybdenum intakes, ranging from 22 μg/day to 1,490 μg/day (almost 1.5 mg/day), elicited no serious adverse effects when molybdenum was given for 24 days (47).

The Food and Nutrition Board (FNB) of the Institute of Medicine (now the National Academy of Medicine) found little evidence that molybdenum excess was associated with adverse health outcomes in generally healthy people. To determine the tolerable upper intake level (UL), the FNB selected adverse reproductive effects in rats as the most sensitive index of toxicity and applied a large uncertainty factor because animal data were used (2). The UL for molybdenum is listed by age group in **Table 2**.

Table 2. Tolerable Upper Intake Level (UL) for Molybdenum

Age Group	UL (μg/day)
Infants 0-12 months	Not possible to establish*
Children 1-3 years	300
Children 4-8 years	600
Children 9-13 years	1,100 (1.1 mg/day)
Adolescents 14-18 years	1,700 (1.7 mg/day)
Adults 19 years and older	2,000 (2.0 mg/day)
*Source of intake should be from food and formula only.	

Drug interactions

High doses of molybdenum have been found to inhibit the metabolism of acetaminophen in rats (64); however, it is not known whether this occurs at clinically relevant doses in humans.

Linus Pauling Institute Recommendation

The RDA for molybdenum (45 μg/day for adults) is sufficient to prevent deficiency. Although the intake of molybdenum most likely to promote optimum health is not known, there is presently no evidence that intakes higher than the RDA are beneficial. Most people in the US consume more than sufficient molybdenum in their diets, making supplementation unnecessary. Following the Linus Pauling Institute's general recommendation to take a multivitamin/mineral supplement that contains 100% of the daily values (DV) for most nutrients is likely to provide 45 μg/day of molybdenum.

Older adults (>50 years)

Because aging has not been associated with significant changes in the requirement for molybdenum (2), our recommendation for older adults is the same as that for adults 50 years and younger.

Summary

- Phosphorus is an essential structural component of cell membranes and nucleic acids but is also involved in several biological processes, including bone mineralization, energy production, cell signaling through phosphorylation reactions, and regulation of acid-base homeostasis. *(More information)*
- Dietary phosphorus deficiency is uncommon and often only observed in cases of near-total starvation or in rare inherited disorders involving renal phosphorus wasting. Symptoms include loss of appetite, muscle weakness, bone fragility, numbness in the extremities, and rickets in children. *(More information)*
- The Recommended Dietary Allowance (RDA), 700 mg/day of phosphorus for healthy adults, is meant to sustain serum phosphorus concentrations within the physiologic range of 2.5 to 4.5 mg/dL. *(More information)*
- Phosphorus is found in most food sources and is a component of many commonly used food additives. The bioavailability of phosphorus from food is usually very high with the exception of phytate phosphorus in plant sources, such as grains, legumes, and seeds, which is poorly digested. *(More information)*
- Estimates of dietary phosphorus intakes in the US population are likely to be inaccurate because the amounts of phosphorus-based food additives used in processed foods are not always included in the nutrient content database used to compute nutrient intakes. *(More information)*
- High serum phosphorus concentrations have been associated with increased rates of cardiovascular disease and mortality in subjects with or without kidney disease. Abnormal deposition of calcium phosphate in soft tissues may predispose individuals to vascular dysfunction and cardiovascular disease. *(More information)*
- Hyperphosphatemia, which is common in individuals with impaired kidney function, characterizes a condition in which there is an abnormally high accumulation of phosphorus in blood, because the kidneys are not able to effectively excrete it. *(More information)*
- The tolerable upper intake level (UL) for phosphorus is 4,000 mg/day for generally healthy adults. Yet, daily phosphorus intakes in excess of the RDA have been linked to an increased risk of all-cause mortality in healthy individuals. *(More information)*
- Observational studies suggest that a low calcium-to-phosphorus intake ratio may be detrimental to bone health, especially in women at increased risk for osteoporosis. *(More information)*

Phosphorus is an essential mineral that is required by every cell in the body for normal function (1). Bound to oxygen in all biological systems, phosphorus is found as phosphate (PO_4^{3-}) in the body. Approximately 85% of the body's phosphorus is found in bones and teeth (2).

Function

Phosphorus is a major structural component of bone in the form of a calcium phosphate salt called hydroxyapatite. Phospholipids (e.g., phosphatidylcholine) are major structural components of cell membranes. All energy production and storage are dependent on phosphorylated compounds, such as adenosine triphosphate (ATP) and creatine phosphate. Nucleic acids (DNA and RNA), which are responsible for the storage and transmission of genetic information, are long chains of phosphate-containing molecules. A number of enzymes, hormones, and cell-signaling molecules depend on phosphorylation for their activation. Phosphorus also helps maintain normal acid-base balance (pH) by acting as one of the body's most important buffers. Additionally, the phosphorus-containing molecule 2,3-diphosphoglycerate (2,3-DPG) binds to hemoglobin in red blood cells and regulates oxygen delivery to the tissues of the body (1).

Regulation

Parathyroid hormone-vitamin D and FGF-23-endocrine axis

Dietary phosphorus is readily absorbed in the small intestine, and in healthy individuals, excess phosphorus is excreted by the kidneys under the regulatory action of the endocrine hormones: parathyroid hormone (PTH), vitamin D, and fibroblast growth factor-23 (FGF-23). The acute regulation of blood calcium and phosphorus concentrations is controlled through the actions of PTH and the active form of vitamin D. A slight drop in blood calcium levels (e.g., in the case of inadequate calcium intake) is sensed by the parathyroid glands, resulting in their increased secretion of PTH, which rapidly decreases urinary excretion of calcium but increases urinary excretion of phosphorus and stimulates bone resorption. This results in the release of bone mineral (calcium and phosphate) — actions that restore serum calcium concentrations. Although the action is not immediate, PTH also stimulates conversion of vitamin D to its active form (1,25-dihydroxyvitamin D; calcitriol) in the kidneys. Increased circulating 1,25-dihydroxyvitamin D in turn stimulates increased intestinal absorption of both calcium and phosphorus. A third hormone, FGF-23, plays a central role in phosphorus homeostasis. FGF-23 is secreted by bone-forming cells (osteoblasts/osteocytes) in response to increases in phosphorus intake. In a negative feedback loop, FGF-23 inhibits the production and stimulates the degradation of 1,25-dihydroxyvitamin D, as well as promotes an increase in urinary phosphorus excretion independently of PTH and 1,25-dihydroxyvitamin D (3).

Deficiency

Inadequate phosphorus intake rarely results in abnormally low serum phosphorus levels (hypophosphatemia) because renal reabsorption of phosphorus increases to compensate for decreased intake. The effects of moderate to severe hypophosphatemia may include loss of appetite, anemia, muscle weakness, bone pain, rickets (in children), osteomalacia (in adults), increased susceptibility to infection, numbness and tingling of the extremities, difficulty walking, and respiratory failure. Severe hypophosphatemia may occasionally be life threatening. Since phosphorus is so widespread in food, dietary phosphorus deficiency is usually seen only in cases of near-total starvation. Other individuals at risk of hypophosphatemia include alcoholics, diabetics recovering from an episode of diabetic ketoacidosis, patients with respiratory alkalosis, and starving or anorexic patients on refeeding regimens that are high in calories but too low in phosphorus (reviewed in 4). Hypophosphatemia caused by inherited disorders of phosphorus homeostasis (phosphorus wasting disorders) has been linked to elevated urinary excretion or impaired renal reabsorption of phosphorus in affected subjects (reviewed in 5).

The Recommended Dietary Allowance (RDA)

The Recommended Dietary Allowance (RDA) for phosphorus is based on the maintenance of normal serum phosphorus levels in adults (2.5-4.5 milligrams/deciliter [mg/dL]) and is believed to represent adequate phosphorus intakes to meet cellular and bone formation needs (6; **Table 1**). The RDA, which is the average daily intake that meets the requirements of 97.5% of healthy individuals in a specific life stage and gender group, is based on the Estimated Average Requirement (EAR; 580 mg/day of phosphorus for adults) — the nutrient intake that meets the requirements of 50% of healthy individuals in a particular life stage and gender group.

Table 1. Recommended Dietary Allowance (RDA) for Phosphorus

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	100 (AI)	100 (AI)
Infants	7-12 months	275 (AI)	275 (AI)
Children	1-3 years	460	460
Children	4-8 years	500	500
Children	9-13 years	1,250	1,250
Adolescents	14-18 years	1,250	1,250
Adults	19 years and older	700	700
Pregnancy	18 years and younger	-	1,250
Pregnancy	19 years and older	-	700
Breast-feeding	18 years and younger	-	1,250
Breast-feeding	19 years and older	-	700

Sources

Food sources

Phosphorus is found in most food because it is a critical constituent of all living organisms. Dairy foods, cereal products, meat, and fish are particularly rich sources of phosphorus (7). Phosphorus is also a component of many food additives that are used in food processing and is present in cola soft drinks as phosphoric acid (8). In the nationally representative NHANES survey, phosphorus intakes were well above the EAR and RDA, with average daily intakes of 1,602 mg in men and 1,128 mg in women (8). Dietary phosphorus derived from food additives is not always included in food nutrient composition databases, so the total amount of phosphorus consumed by the average person in the US can be underestimated by more than 20% (9). Segments of the US population who consume more highly processed foods and whose phosphorus intakes approach the tolerable upper intake level of 4,000 mg/day are thought by some to be at high risk of developing adverse health outcomes (see Safety) (7, 9).

Bioavailability

The phosphorus in plant seeds (beans, peas, cereals, and nuts) is present in a storage form of phosphate called phytic acid or phytate. Only about 50% of the phosphorus from phytate is available to humans because we lack enzymes (phytases) that liberate phosphorus from phytate (10). Yeasts possess phytases, so whole grains incorporated into leavened breads have more bioavailable phosphorus than whole grains incorporated into breakfast cereals or flat breads (6). Because reducing dietary phosphorus absorption may benefit individuals with impaired kidney function who are at risk of hyperphosphatemia (serum phosphorus at or above the high-normal range), protein sources of phosphorus in grain-based vegetarian diets may be preferred over meat-based diets (11). **Table 2** lists a number of phosphorus-rich foods, along with their phosphorus content in milligrams (mg). For more information on the nutrient content of food, search USDA's FoodData Central.

Table 2. Some Food Sources of Phosphorus

Food	Serving	Phosphorus (mg)
Salmon (chinook, cooked)	3 ounces*	315
Yogurt (plain, nonfat)	8 ounces	306
Milk (skim)	8 ounces	247
Halibut (Atlantic or Pacific, cooked)	3 ounces	244
Turkey (light meat, cooked)	3 ounces	217
Chicken (light meat, cooked)	3 ounces	135-196
Beef (chuck eye steak, cooked)	3 ounces	179
Lentils# (cooked)	½ cup	178
Almonds#	1 ounce (23 nuts)	136
Cheese, mozzarella (part skim)	1 ounce	131
Peanuts#	1 ounce	108
Egg (hard-boiled)	1 large	86
Bread, whole-wheat	1 slice	68
Carbonated cola drink	12 ounces	41
Bread, enriched white	1 slice	25
*A three-ounce serving of meat or fish is about the size of a deck of cards. #Phosphorus from nuts, seeds, and grains is about 50% less bioavailable than phosphorus from other sources (12).		

Supplements

Phosphorus content of multivitamin/mineral (MVM) supplements varies; a US national survey found that MVM supplements contributed an average of 108 mg to daily phosphorus intake (10). Sodium phosphate and potassium phosphate salts are used for the treatment of hypophosphatemia that occurs in hereditary disorders of phosphate wasting, and their use requires medical supervision. Calcium phosphate salts are sometimes used as calcium supplements (13). Commonly used over-the-counter and prescription drugs also contribute to phosphorus intakes at levels yet to be defined (10).

Safety

Toxicity

Several disorders characterized by serum phosphorus levels above normal (hyperphosphatemia) have been described, including those resulting from increased intestinal absorption of phosphate salts taken by mouth or by colonic absorption of the phosphate salts in enemas (1). Yet, the disruption of phosphorus homeostasis is most often associated with excretion failure in patients with chronic kidney disease (CKD) or end-stage renal disease (advanced CKD). When kidney function is only 20% of normal, even phosphorus intakes within the recommended range may lead to hyperphosphatemia. Hyperphosphatemia may also affect individuals with inappropriately low parathyroid hormone (PTH) levels (hypoparathyroidism) as they lack PTH stimulation of renal phosphate excretion and fail to stimulate synthesis of 1,25-dihydroxyvitamin D (the active form of vitamin D). These individuals cannot excrete excess phosphorus in the absence of both hormones (14). Elevated serum phosphorus concentrations have been associated with accelerated disease progression in individuals with impaired kidney function and have been linked to increased risk of adverse health outcomes in the general population (9, 15).

High serum phosphorus concentrations in the general population

High serum phosphorus within the normal range (2.5-4.5 mg/dL) has recently been associated with increased incidence of cardiovascular disease (CVD) in individuals with normal kidney function. Two studies conducted in the general population and in individuals with prior CVD have linked high-normal serum phosphorus concentrations (≥3.5 mg/dL) to a greater cardiovascular risk (16, 17). Additional observational studies found that serum phosphorus concentrations equal to or above 4 mg/dL were associated with a doubling of the risk of developing incident CKD and end-stage renal disease in individuals free of renal disease at study inception (18). In a prospective cohort study, which followed 4,005 healthy young adults for more than 15 years, higher serum phosphorus within the normal range was also associated with left ventricular hypertrophy, a condition often linked to adverse cardiovascular outcomes (19). In another study of 3,088 middle-aged healthy participants followed for over 17 years, serum phosphorus concentrations in the top quartile of the normal range were associated with a two-fold higher risk of heart failure compared to the lowest quartile (≥3.5 mg/dL vs. <2.9 mg/dL) (16). It is thought that vascular calcification, which may explain the relationship between high phosphorus and cardiovascular disease risk in CKD patients (see Hyperphosphatemia in subjects with kidney disease), contributes to this association in individuals with normal kidney function, even when their serum phosphorus is within the normal range and their intakes are below the tolerable upper intake level (UL) (20, 21).

Phosphorus homeostasis is tightly regulated by the PTH/vitamin D/FGF-23 axis in individuals with normal kidney function (see Regulation). Increased secretion of PTH and FGF-23 helps maintain phosphorus serum concentrations in the normal range (2.5-4.5 mg/dL) even in the setting of high phosphorus intake (9). This contributes to serum phosphorus being only weakly correlated to phosphorus consumption (22). Of note, sustained increases in FGF-23 and PTH are commonly observed during CKD in order to maintain normal serum phosphorus concentrations despite a reduction in urinary phosphorus excretion (23). Elevated FGF-23, rather than serum phosphorus, appears to be an early marker of disordered phosphorus homeostasis and a predictor of adverse health outcomes in patients with early-stage CKD (23, 24). Thus, it is reasonable to assume that measuring serum phosphorus in people with normal renal function cannot adequately reflect early disturbances in phosphorus metabolism due to high phosphorus consumption.

Hyperphosphatemia in subjects with kidney disease

Observational studies have reported high rates of mortality and cardiovascular events in association with high blood phosphorus levels in subjects with CKD. A meta-analysis of 13 prospective cohort studies, conducted in over 90,000 CKD patients, found an 18% increase in all-cause mortality per 1 mg/dL increase in serum phosphorus concentration above 3.5 mg/dL. A 10% increased risk in cardiovascular disease (CVD)-related death was also calculated for each 1 mg/dL higher concentration in the meta-analysis of three studies (25).

Although no causality has been established between vitamin D deficiency and CVD risk, it has been suggested that failure to produce 1,25-dihydroxyvitamin D in hyperphosphatemic individuals may modify the risk of developing cardiovascular and renal disease, as well as worsen kidney insufficiency in CKD patients (26). Another plausible mechanism for hyperphosphatemia-induced cardiovascular dysfunction is the deposition of calcium phosphate in non-skeletal tissues, especially the vasculature (27). Indeed, high phosphorus concentrations may stimulate the expression of bone specific markers in blood vessel-forming cells, resulting in a shift in their functions; this process, called osteochondrogenic differentiation, transforms vascular smooth muscle cells (VSMCs) into bone-like cells. The culture of human aortic VSMCs in hyperphosphatemic conditions was found to result in the mineralization of the extracellular media, mimicking *in vivo* vascular calcification (28). Vascular calcification has been associated with at least a three-fold increase in risk for cardiovascular events and mortality; the risk for cardiovascular events is twice as high (i.e., six-fold increased risk) in individuals with kidney insufficiency (29).

In CKD patients, disorders in bone remodeling may result in excess release of phosphorus and calcium into the blood, which exacerbates hyperphosphatemia and vascular calcification and accelerates the decline of kidney function. Currently, dietary phosphorus restriction is recommended to normalize serum concentrations in CKD patients, although the impact on CVD and mortality risks is not known.

The Tolerable Upper Intake Level (UL)

To avoid the adverse effects of hyperphosphatemia, the US Food and Nutrition Board set a tolerable upper intake level (UL) for oral phosphorus in generally healthy individuals (6; **Table 3**). The lower UL for individuals over 70 years of age, compared to younger age groups, reflects the increased likelihood of impaired kidney function in elderly individuals. The UL does not apply to individuals with significantly impaired kidney function or other health conditions known to increase the risk of hyperphosphatemia.

Table 3. Tolerable Upper Intake Level (UL) for Phosphorus

Age Group	UL (mg/day)
Infants 0-12 months	Not possible to establish*
Children 1-3 years	3,000 (3.0 g)
Children 4-8 years	3,000 (3.0 g)
Children 9-13 years	4,000 (4.0 g)
Adolescents 14-18 years	4,000 (4.0 g)
Adults 19-70 years	4,000 (4.0 g)
Adults 71 years and older	3,000 (3.0 g)
Pregnancy	3,500 (3.5 g)
Breast-feeding	4,000 (4.0 g)
*Source of intake should be from food and formula only.	

Adverse health outcomes have been associated with normal serum phosphorus concentrations, suggesting that in individuals with adequate kidney function, the measurement of tightly controlled serum phosphorus levels may misrepresent the detrimental effect of high dietary phosphorus intake (see High serum phosphorus concentrations in the general population). While phosphorus intakes below the UL of 4,000 mg/day should not result in hyperphosphatemia or cardiovascular risk in healthy adults ages 19-70 years, a recent study found that daily phosphorus intakes more than twice the RDA (i.e., >1,400 mg/day) were significantly associated with an increased risk of all-cause mortality (30).

Is high phosphorus intake detrimental to bone health?

Some investigators are concerned about the increasing amounts of phosphates in the diet, which they largely attribute to phosphoric acid in some soft drinks and the increasing use of phosphate additives in processed foods (31, 32). High serum phosphorus has been shown to impair synthesis of the active form of vitamin D (1,25-dihydroxyvitamin D) in the kidneys, reduce blood calcium, and lead to increased PTH release by the parathyroid glands (8). PTH stimulation then results in decreased urinary calcium excretion and increased bone resorption; both contribute to serum calcium concentrations returning to normal (8). If sustained, elevated PTH levels could have an adverse effect on bone mineral content, but this effect appears to be observed with diets that are high in phosphorus and low in calcium, underscoring the importance of a balanced dietary calcium-to-phosphorus ratio. In a small cross-sectional study, which enrolled 147 premenopausal women with adequate calcium intakes, participants with lower calcium-to-phosphorus (Ca:P) intakes (ratios ≤0.5) had significantly higher serum PTH levels and urinary calcium excretion than those with higher Ca:P ratios (ratios >0.5) (33). A controlled trial in 10 young women found no adverse effects of a phosphorus-rich diet (3,000 mg/day) on bone-related hormones and biochemical markers of bone resorption when dietary calcium intakes were maintained at almost 2,000 mg/day (Ca:P = 0.66), again demonstrating the importance of the balance between dietary calcium and phosphorus (34).

A cross-sectional study conducted in 2,344 Brazilian men and women (median age, 58 years) showed an association between higher phosphorus intakes and increased risk of fracture. Yet, intakes of other minerals and vitamins relevant to bone health, such as calcium, magnesium, and vitamin D, were below the RDA in this population, whereas phosphorus intakes were close to the RDA (35). While it appears that hormonal and calcium disorders might be prevented by an adequate calcium-to-phosphorus intake ratio, there is no convincing evidence that the dietary phosphorus levels experienced in the US adversely affect bone mineral density. Nevertheless, the substitution of phosphate-containing soft drinks and snack foods for milk and other calcium-rich food may represent a serious risk to bone health (see the article on Calcium) (36).

Drug interactions

Aluminum-containing antacids reduce the absorption of dietary phosphorus by forming aluminum phosphate, which is unabsorbable. When consumed in high doses, aluminum-containing antacids can produce abnormally low blood phosphorus levels (hypophosphatemia), as well as aggravate phosphorus deficiency due to other causes (37). The reduction of stomach acidity by proton-pump inhibitors may also limit the efficacy of phosphate-binder therapy in patients with kidney failure (38). Excessively high doses of 1,25-dihydroxyvitamin D, the active form of vitamin D, or its analogs, may result in hyperphosphatemia (6).

Potassium supplements or potassium-sparing diuretics taken together with phosphorus supplements may result in high blood levels of potassium (hyperkalemia). Hyperkalemia can be a serious problem, resulting in life-threatening heart rhythm abnormalities (arrhythmias). People taking such a combination must inform their health care provider and have their serum potassium levels checked regularly (37).

Additionally, prevention of bone demineralization by hormone replacement therapy in postmenopausal women is associated with higher urinary phosphorus excretion and lower serum phosphorus levels in treated compared to untreated women (39, 40).

Linus Pauling Institute Recommendation

The Linus Pauling Institute supports the RDA for phosphorus (700 mg/day for adults). Although some multivitamin/mineral supplements contain more than 15% of the current RDA for phosphorus, a varied diet should easily provide adequate phosphorus for most people.

Older adults (>50 years)

At present, there is no evidence that phosphorus requirements of older adults differ from that of younger adults, and a varied diet should easily provide the RDA (700 mg/day) of phosphorus for those over 50 years of age.

Summary

- Potassium is considered to be a "nutrient of public health concern" according to the 2015-2020 Dietary Guidelines for Americans since its underconsumption in the US population is associated with adverse health effects (hypertension and cardiovascular disease). *(More information)*
- Normal body function depends on tight regulation of potassium concentrations both inside and outside of cells. *(More information)*
- Low potassium concentration in blood (hypokalemia) can result in muscular paralysis or abnormal heart rhythms and can be fatal. Hypokalemia is usually due to excessive loss of potassium as with prolonged vomiting or diarrhea, use of diuretics, or with kidney disease. *(More information)*
- Chronic hypertension damages the heart, blood vessels, and kidneys, thereby increasing the risk of cardiovascular disease. Increasing dietary potassium intake may help lower blood pressure in normotensive and hypertensive individuals. *(More information)*
- Results from observational studies reported higher dietary potassium intakes to be associated with lower risks of stroke and kidney stone formation. Evidence of a role for potassium intakes in promoting bone health remains weak. *(More information)*
- The adequate intake (AI) for potassium is 2,600 mg/day for women and 3,400 mg/day for men. The AI for each age/life stage group was set based on the level of intake reported in apparently healthy populations. *(More information)*
- Good dietary sources of potassium include fruit and vegetables, some nuts and seeds, and dairy products. *(More information)*
- Safety concerns with consuming potassium are limited in healthy people because the kidneys adjust urinary potassium excretion to potassium intake. Concomitant use of potassium supplements with certain drugs can increase the risk of potassium toxicity. *(More information)*

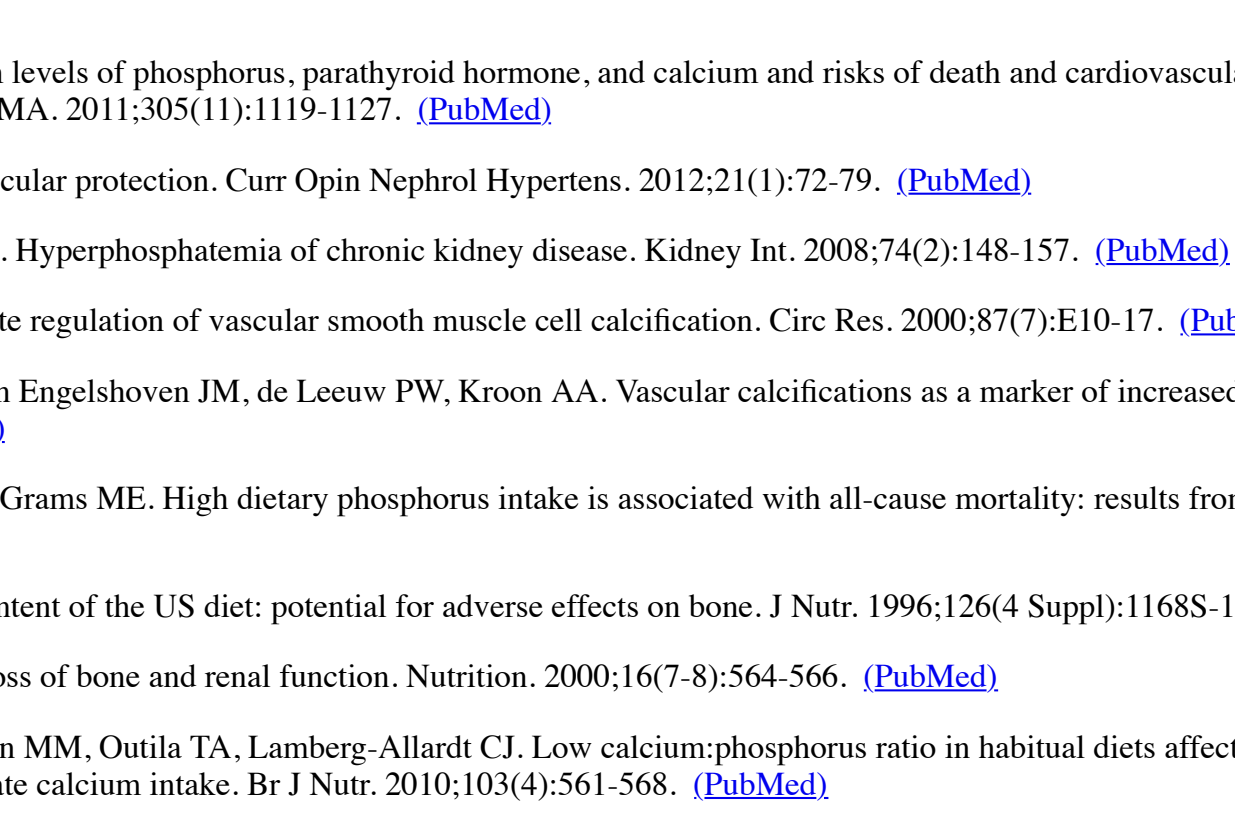
Potassium is an essential dietary mineral and electrolyte. The term electrolyte refers to a substance that dissociates into ions (charged particles) in solution, making it capable of conducting electricity. Normal body function depends on tight regulation of potassium concentrations both inside and outside of cells (1).

Function

Maintenance of membrane potential

Potassium (K^+) is the principal positively charged ion (cation) in the fluid inside of cells, while sodium (Na^+) is the principal cation in the extracellular fluid. Potassium concentrations are about 30 times higher inside than outside cells, while sodium concentrations are more than 10 times lower inside than outside cells. The concentration differences between potassium and sodium across cell membranes create an electrochemical gradient known as the membrane potential. A cell's membrane potential is maintained by ion pumps in the cell membrane, especially the Na^+/K^+-ATPase pumps. These pumps use ATP (energy) to pump sodium out of the cell in exchange for potassium (**Figure 1**). Their activity has been estimated to account for 20%-40% of the resting energy expenditure in a typical adult. The large proportion of energy dedicated to maintaining sodium/potassium concentration gradients emphasizes the importance of this function in sustaining life. Tight control of cell membrane potential is critical for nerve impulse transmission, muscle contraction, and heart function (2-4).

Figure 1. A Simplified Model of the Na^+/K^+ATPase Pump



Differences in concentrations of potassium (K^+) and sodium (Na^+) ions across cell membranes create an electrochemical gradient known as the membrane potential. The concentration of K^+ is typically 20-30 times higher inside compared to outside the cells whereas Na^+ is in higher concentration in the extracellular compared to the intracellular compartment. Therefore, K^+ diffuses easily out of the cells whereas Na^+ diffuses easily into the cells. The Na^+/K^+ ATPase pump is thus required to maintain the membrane potential by pumping Na^+ out of the cells and K^+ into the cells. In the presence of magnesium (Mg^{2+}), adenosine triphosphate (ATP) provides the energy to translocate 3 Na^+ ions and 2 K^+ ions across the plasma membrane against their concentration gradients. The binding of ATP and magnesium (Mg^{2+}) allows the enzyme to adopt a conformation that opens toward the cytoplasm for the binding and the translocation of Na^+ ions; In turn, the binding of K^+ ions induces the release of phosphate and Mg^{2+} and the translocation of K^+ ions to the cytoplasm.

[Figure 1 - Click to Enlarge]

Cofactor for enzymes

A limited number of enzymes require the presence of potassium for their activity. The activation of Na^+/K^+-ATPase requires the presence of sodium and potassium. The presence of potassium is also required for the activity of pyruvate kinase, an important enzyme in carbohydrate metabolism (5).

Deficiency

An abnormally low plasma potassium concentration is referred to as hypokalemia. Hypokalemia is most commonly a result of excessive loss of potassium, e.g., from prolonged vomiting or diarrhea, use of some diuretics and other medications (see Drug interactions), some forms of kidney disease, or metabolic disturbances. The symptoms of hypokalemia are related to alterations in membrane potential and cellular metabolism (1). They include fatigue, muscle weakness and cramps, and intestinal paralysis, which may lead to bloating, constipation, and abdominal pain. Chronic hypokalemia is associated with hypertension and kidney stone formation (see Disease Prevention and Disease Treatment). Severe hypokalemia may result in muscular paralysis or abnormal heart rhythms (cardiac arrhythmias) that can be fatal (1, 6).

Conditions that increase the risk of hypokalemia (see also Drug interactions; 1):

- The use of potassium-wasting diuretics (e.g., thiazide diuretics or furosemide)
- Prolonged vomiting or diarrhea
- Overuse or abuse of laxatives
- Anorexia nervosa or bulimia
- Excessive sweating
- Nephropathies
- Polyuria
- Abnormally high production of aldosterone (hyperaldosteronism)
- Magnesium depletion
- Recovery from prolonged undernutrition

Low dietary potassium intake alone does not generally result in hypokalemia. However, insufficient dietary potassium in patients at risk of hypokalemia can precipitate hypokalemia (1).

In rare cases, habitual consumption of large amounts of black licorice has resulted in hypokalemia (7, 8). Licorice contains a compound (i.e., glycyrrhizic acid) with similar physiologic effects to those of aldosterone, a hormone that increases urinary excretion of potassium.

The Adequate Intake (AI)

The Dietary Reference Intakes (DRIs) for potassium have been recently revised by the Food and Nutrition Board (FNB) of the National Academy of Medicine. The FNB did not find sufficient evidence to determine an Estimated Average Requirement (EAR) and derive a Recommended Dietary Allowance (RDA); instead, they established an adequate intake (AI) based on median intakes in generally healthy people (**Table 1**) (9). The FNB found insufficient evidence from human studies that examined potassium intakes in relation to chronic disease and mortality (reviewed recently by the Agency for Healthcare Research and Quality; 10) to inform the DRIs for potassium (11).

Table 1. Adequate Intake (AI) for Potassium

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	400	400
Infants	7-12 months	860	860
Children	1-3 years	2,000	2,000
Children	4-8 years	2,300	2,300
Children	9-13 years	2,500	2,300
Adolescents	14-18 years	3,000	2,300
Adults	19 years and older	3,400	2,600
Pregnancy	14-18 years	-	2,600
Pregnancy	19-50 years	-	2,900
Breast-feeding	14-18 years	-	2,500
Breast-feeding	19-50 years	-	2,800

Disease Prevention

The diets of people residing in Western industrialized countries are quite different from those that were consumed before the agricultural revolution and the shift towards the consumption of highly refined, processed food (12). Among other differences, the daily intake of sodium chloride (salt) in modern diets is about three times higher than the daily intake of potassium on a molar basis, whereas salt intake in primitive cultures is about seven times lower than potassium intake (13). The relative deficiency of dietary potassium in the modern diet and a higher sodium-to-potassium ratio may contribute to the development of some chronic diseases.

Stroke

Observational studies have consistently reported an increased risk of cardiovascular disease with elevated dietary sodium intakes (14, 15). Several prospective cohort studies have also found an inverse association between potassium intake and risk of stroke. A meta-analysis of nine prospective cohort studies showed that daily potassium intakes ranging between 3,510 mg and 4,680 mg were associated with a 30% reduced risk of stroke (16). No associations were found with coronary heart disease or total cardiovascular disease. In a more recent meta-analysis of 16 studies, the highest versus lowest dietary potassium intake was found to be associated with a 13% lower risk of stroke after multiple adjustments (including for blood pressure) (17). The lowest risk of stroke corresponded to daily potassium intakes around 3,500 mg. Subgroup analyses showed a reduced risk of ischemic stroke, but not hemorrhagic stroke. Finally, in a recent meta-analysis of 16 observational studies, each 1-unit increase in the dietary sodium-to-potassium ratio was found to be associated with a 22% higher risk of stroke (12).

Kidney stones

Abnormally high urinary calcium (hypercalciuria) increases the risk of developing kidney stones. In individuals with a history of developing calcium-containing kidney stones, increased dietary acid load has been significantly associated with increased urinary calcium excretion (18). Increasing dietary potassium (and alkali) intake by increasing fruit and vegetable intake or by taking potassium bicarbonate ($KHCO_3$) supplements has been found to decrease urinary calcium excretion. Conversely, potassium deprivation has been found to increase urinary calcium excretion (19, 20).

Three large US prospective cohort studies — the Health Professionals Follow-up Study and the Nurses' Health Studies I and II — which included 193,676 participants, have examined dietary potassium intake and animal protein-to-potassium ratio (a marker of dietary acid load) in the diet in relation to the risk of developing kidney stones (21). In all three cohorts, dietary potassium intake was derived almost entirely from potassium-rich foods, such as fruit and vegetables. Across the three cohorts, individuals in the highest quintile of potassium intake were found to be 33%-56% less likely to develop symptomatic kidney stones than those in the lowest quintile of intake. Additionally, a pooled analysis of the data from all three cohorts showed that those with the highest versus lowest animal protein-to-potassium ratio were 41% more likely to develop kidney stones (21).

Urinary alkalinization with supplemental potassium citrate is used in stone formers to reduce the risk of recurrent stone formation (reviewed in 22). However, potassium citrate therapy should only be initiated under the supervision of a medical provider.

Osteoporosis

In a 2015 case-cohort study nested within the European Prospective Investigation into Cancer and Nutrition (EPIC)-Norfolk study, which included 5,319 individuals, dietary intakes of potassium (alone or combined with intakes of magnesium) were found to be inversely associated with heel bone (calcaneus) broadband ultrasound attenuation (BUA) measurements (a predictor of the risk of incidental fracture) and risk of hip fracture in women but not in men (23). More recently, a cross-sectional study in older Korean adults reported higher total hip and femur neck bone mineral density (BMD) in those in the top versus bottom tertile of potassium intakes (24). Although these observational studies suggest a link between potassium intakes and bone health, they cannot establish whether there is a cause-and-effect relationship.

The mechanisms by which potassium might influence bone health are poorly understood. Modern (Western) diets tend to be relatively low in sources of alkali (fruit and vegetables) and high in sources of acid (fish, meat, and cheese) (25). When the quantity of bicarbonate ions is insufficient to maintain normal pH, the body is capable of mobilizing alkaline calcium salts from bone in order to neutralize acids consumed in the diet or generated by metabolism (26). Because fruit and vegetables are rich in both potassium and precursors to bicarbonate ions, increasing their consumption might help reduce the net acid content of the diet and preserve calcium in bones, which might otherwise be mobilized to maintain normal pH (see the article on Fruit and Vegetables).

Alternatively, potassium bicarbonate supplementation might decrease urinary acid and calcium excretion and influence bone turnover — a small trial in postmenopausal women found that potassium bicarbonate supplementation increases biomarkers of bone formation and a decreased biomarkers of bone resorption (27). A two-year randomized, double-blind, controlled trial in 201 older adults without osteoporosis (mean age, 69 years) found evidence of increased lumbar spine, hip, femoral neck, and total-body BMD, as well as trabecular BMD of the radius and tibia, with supplemental potassium citrate (2,340 mg/day) compared to placebo (28). Potassium citrate was also found to increase the serum concentration of N-terminal propeptide of type I procollagen (PINP) — a marker of bone formation — and reduce the urine concentration of N-telopeptide of collagen type I (NTX) — a marker of bone resorption (28). Another three-month, randomized, placebo-controlled trial in 244 adults (≥50 years) examined the effect of oral potassium bicarbonate, at either 39 mg/kg/day or 58.5 mg/kg/day, on markers of bone turnover (29). Both dosage regimens led to reductions in serum PINP concentration and urine NTX concentration, yet evidence of an effect was stronger with the lowest dose (median dose administered, 3,160 mg/day) rather than with the highest dose (median dose administered, 4,760 mg/day). In contrast, a two-year randomized controlled trial found that neither supplementation with potassium citrate (721 mg/day or 2,165 mg/day) nor an increase in fruit and vegetable intake (300 mg/day) had an impact on markers of bone turnover or increased BMD in postmenopausal women (30). A 2015 meta-analysis of intervention studies found that supplemental potassium citrate or potassium bicarbonate could reduce urinary net acid and calcium excretion, but evidence to support an effect on markers of bone turnover and bone density was weak (31). The most recent randomized, double-blind, controlled trial in 40 postmenopausal women with osteopenia found no difference in markers of bone turnover over a six-month period between those supplemented with potassium citrate and those taking a placebo (32). The authors highlighted the possibility that an effect of supplemental potassium might have an impact on bone health in a subset of subjects with low potassium intakes and/or signs of low-grade acidosis. In this study, all participants received daily supplements of calcium carbonate (500 mg/day) and vitamin D (10 μg/day).

Overall, whether consuming potassium-rich fruit and vegetables can influence bone health and help lower the risk of osteoporosis remains uncertain (see also the article on Fruit and Vegetables).

Disease Treatment

Hypertension

Forty-five percent of US adults have hypertension (blood pressure levels ≥130/80 mm Hg) (33). Chronic hypertension damages the heart, blood vessels, and kidneys, thereby increasing the risk of heart disease and stroke, as well as hypertensive kidney disease (34, 35). Modern diets, which are high in sodium and low in potassium, are recognized as largely contributing to the high prevalence of hypertension (see the article on Sodium). Unlike 24-hour dietary recalls, 24-hour urine collections provide accurate estimates of dietary intakes of sodium and potassium (36). An analysis of the 2014 US National Health and Nutrition Examination Survey (NHANES) showed an increase in systolic blood pressure with increasing sodium excretion and increasing sodium-to-potassium ratio in the urine (37). In this study, the highest versus lowest quartile of urinary potassium excretion (mid-values, 3,043 mg/day versus 1,484 mg/day) was associated with a 62% lower risk of hypertension (37).

The Dietary Approaches to Stop Hypertension (DASH) trial provided evidence of the blood pressure-lowering effect of a diet higher in potassium and calcium, modestly higher in protein, and lower in total fat, saturated fat, cholesterol, red meat, sweets, and sugar-containing beverages compared to the typical US diet (38). Indeed, compared to the control diet providing only 3.5 servings/day of fruit and vegetables and 1,700 mg/day of potassium, adherence to the DASH diet that included 8.5 servings/day of fruit and vegetables and 4,100 mg/day of potassium lowered systolic/diastolic blood pressures by an average 11.4/5.5 mm Hg in people with hypertension and 3.5/2.1 mm Hg in those without hypertension (38). A 2014 meta-analysis of 17 randomized controlled trials that examined the effect of the DASH diet compared to a control diet in a total of 2,561 adults found overall reductions in systolic and diastolic blood pressure by 6.7 mm Hg and 3.5 mm Hg, respectively (39). However effective the DASH diet is, the blood pressure-lowering effects can hardly be solely attributed to potassium intakes (40).

A 2015 meta-analysis of 15 randomized controlled trials, including 917 individuals, assessed the effects of increased potassium intake, mostly in the form of potassium chloride (KCl) supplements, on blood pressure (41). Thirteen studies included hypertensive participants who were not taking anti-hypertensive medication and two studies included normotensive or at-risk subjects. Most studies used supplemental potassium doses between 2,340 and 2,535 mg/day (60-65 mmol/L). Increased potassium intake resulted in overall reductions of systolic blood pressure by 4.7 mm Hg and diastolic blood pressure by 3.5 mm Hg. The blood pressure-lowering effect of supplemental potassium was more pronounced when the analysis was restricted to individuals with hypertension: systolic and diastolic blood pressure were found to be reduced by 6.8 mm Hg and 4.6 mm Hg, respectively (41). Two additional meta-analyses published in 2017 also confirmed a blood pressure-lowering effect of supplemental potassium. Findings suggested some evidence of a greater effect when baseline potassium intake was less than 3,510 mg/day (vs. ≥3,510 mg/day [90 mmol]) (42). Meta-analyses have also reported a dose-response relationship between the intake of potassium and the lowering of blood pressure (42, 43).

Supplemental potassium can help lower blood pressure, but potassium supplements should only be used in consultation with a medical provider (see Supplements). Increasing potassium intake to recommended levels (see Adequate Intake) by consuming a diet rich in fruit and vegetables can help lower blood pressure and may have additional benefits to health (see the article on Fruit and Vegetables). Blood pressure is a reliable cardiovascular risk marker (44). Yet, although reducing sodium consumption while increasing potassium intake helps with lowering blood pressure (45), current evidence suggests that dietary advice and support interventions may not be sufficient to deliver long-term cardiovascular benefits in individuals with hypertension (46).

Sources

Food sources

The richest sources of potassium are fruit and vegetables. Nuts, seeds, and dairy products are also good sources of potassium. A dietary survey in the US indicated that the average dietary potassium intake was 2,408 mg/day for adult women and 3,172 mg/day for adult men (47). Because many individuals in the population consume potassium in amounts that are well below the AI and because underconsumption of potassium is linked with adverse health effects, potassium has been recognized as a "nutrient of public health concern" in the 2015-2020 Dietary Guidelines for Americans. In 2016, the US Food and Drug Administration (FDA) required manufacturers to display potassium content of foods on the Nutrition Facts food label (48).

Some relatively good dietary sources of potassium are listed in the **Table 2**, along with their potassium content in milligrams (mg). For more information on the nutrient content of foods, search USDA's FoodData Central (49).

Table 2. Some Food Sources of Potassium

Food	Serving	Potassium (mg)
Potato, baked, with skin	1 medium	926
Apricots, dried	½ cup	755
Beet greens, cooked, boiled	½ cup	654
Plums, dried (prunes)	½ cup	637
Raisins	½ cup	598
Yogurt, plain, low-fat	8 ounces	531
Lima beans, cooked	½ cup	478
Acorn squash, cooked	½ cup (cubes)	448
Banana	1 medium	422
Spinach, cooked	½ cup	419
Tomato juice	6 fluid ounces	395
Orange juice	6 fluid ounces	372
Artichoke, cooked	1 medium	343
100% Prune juice	6 fluid ounces	322
Molasses	1 tablespoon	293
Tomato	1 medium	292
Pistachios	1 ounce	285
Milk	8 ounces	281
Orange	1 medium	238
Almonds	1 ounce	208
Sunflower seeds	1 ounce	137
Egg, whole, cooked	1 large	81

Supplements

Multivitamin-mineral supplements in the US do not contain more than 99 mg of potassium per serving (50). One milliequivalent (mEq) or one millimole (mmol) corresponds to about 39 mg of potassium. Higher doses of supplemental potassium are generally prescribed to prevent and treat potassium depletion and hypokalemia. The use of more potent potassium supplements in potassium deficiency requires close monitoring of serum potassium concentrations. Potassium is available in different supplemental forms, including potassium chloride, potassium citrate, potassium gluconate, potassium bicarbonate, potassium aspartate, and potassium orotate (50). Because of the potential for serious side effects, one should seek medical advice before deciding to use a potassium supplement (see Safety). The best way to increase one's potassium intake is by increasing the consumption of potassium-rich food and beverages (50).

Finally, many salt substitutes contain potassium chloride, and acesulfame potassium (Ace-K) is an FDA-approved general purpose sweetener.

Safety

Toxicity

Abnormally elevated serum potassium concentrations are referred to as hyperkalemia. Hyperkalemia occurs when potassium intake exceeds the capacity of the kidneys to eliminate it. Acute or chronic kidney failure, the use of potassium-sparing diuretics, and insufficient aldosterone secretion (hypoaldosteronism) may result in the accumulation of potassium due to a decreased urinary potassium excretion. Oral doses of potassium >18 g taken at one time in individuals not accustomed to high intakes may lead to severe hyperkalemia, even in those with normal kidney function (6, 50). Hyperkalemia may also result from a shift of intracellular potassium into the circulation, which may occur with the rupture of red blood cells (hemolysis) or tissue damage (e.g., trauma or severe burns). Symptoms of hyperkalemia may include tingling of the hands and feet, muscular weakness, and temporary paralysis. The most serious complication of hyperkalemia is the development of an abnormal heart rhythm (cardiac arrhythmia), which can lead to cardiac arrest (51). A meta-analysis of randomized controlled studies showed that heart rate in healthy adults was unlikely to be affected by the chronic use of supplemental potassium doses of 2 to 3 g/day (52).

See the section on Drug interactions for a discussion of the medications that increase the risk of hyperkalemia.

Adverse reactions to potassium supplements

Gastrointestinal symptoms are the most common side effects of potassium supplements, including nausea, vomiting, abdominal discomfort, and diarrhea. Intestinal ulceration has been reported after the use of enteric-coated potassium chloride tablets. Taking potassium with meals or taking a microencapsulated form of potassium may reduce gastrointestinal side effects (50). Rashes may occasionally occur. The most serious adverse reaction to potassium supplementation is hyperkalemia, yet is rare in subjects with normal kidney function (see Toxicity). Individuals with abnormal kidney function and those on potassium-sparing medications (see Drug interactions) should be monitored closely to prevent hyperkalemia (50, 53).

Drug interactions

Table 3 lists the classes of medications known to increase the risk of hyperkalemia (elevated serum potassium) in patients who also use potassium supplements (50, 51, 54).

Table 3. Medications Associated with Hyperkalemia

Medication Family	Specific Medications
Angiotensin converting enzyme (ACE) inhibitors	captopril (Capoten), enalapril (Vasotec), fosinopril (Monopril), ramipril (Altace)
Angiotensin receptor blockers	Losartan (Cozaar), valsartan (Diovan), irbesartan (Avapro), candesartan (Atacand)
Anticoagulant	Heparin
Anti-hypertensive agents	β-blockers, α-blockers
Anti-infective agents	Trimethoprim-sulfamethoxazole, pentamidine
Cardiac glycoside	Digitalis
Nonsteroidal anti-inflammatory agents (NSAID)	Indomethacin, ibuprofen, ketorolac
Potassium-sparing diuretics	spironolactone (Aldactone), triamterene (Dyrenium), amiloride (Midamor)

Several classes of medications are known to induce hypokalemia (low serum potassium; **Table 4**; 55) . In the absence of treatment, hypokalemia can have serious complications and even be fatal (see Deficiency). Various mechanisms explain how certain medications can lead to potassium depletion. For example, both loop and thiazide diuretics increase the urinary excretion of potassium. Corticoids cause sodium retention that leads to a compensatory increase in urinary potassium excretion. Penicillins formulated as sodium salts also stimulate potassium excretion. Several medications, including aminoglycosides, anti-fungal agents (amphotericin-B, fluconazole), and cisplatin, can damage the renal tubular epithelium and lead to severe potassium loss. Outdated tetracycline antibiotics have been linked to electrolyte disturbances.

Table 4. Medications Associated with Hypokalemia

Medication Family	Specific Medications
Aminoglycosides	amikacin (Amikin), gentamicin (Garamycin), kanamycin (Kantrex), tobramycin (Nebcyn), streptomycin
Antibiotics	*Penicillins*: penicillin G sodium (Pfizerpen), mezlocillin (Mezlin), carbenicillin (Geocillin), ticarcillin (Ticar) *Tetracyclines* (when outdated)
Anti-cancer agent	cisplatin (Platinol-AQ)
Anti-fungal agents	amphotericin B (Abelcet, Amphotec, AmBisome, Amphocin, Fungizone), fluconazole (Diflucan)
β-adrenergic agonists	albuterol (Salbutamol, Ventolin), bitolterol (Tornalate), metaproterenol (Alupent)
Diuretics	*Loop diuretics*: bumetanide (Bumex), ethacrynic acid (Edecrin), furosemide (Lasix), torsemide (Demadex) *Thiazide diuretics*: Acetazolamide, thiazides, chlorthalidone (Hygroton), indapamide (Lozol), metolazone (Zaroxolyn), chlorothiazide (Diuril)
Mineralocorticoids	fludrocortisone (Florinef), hydrocortisone (Cortef), cortisone (Cortone), prednisone (Deltasone) *Substances with mineralocorticoid effects*: licorice, carbenoxolone, gossypol
Other	methylxanthines (e.g., theophylline), sodium polystyrene sulfonate, sodium phosphates, caffeine

Linus Pauling Institute Recommendation

There is substantial evidence suggesting that a diet high in potassium-rich food and beverages may be associated with lower risks of stroke, hypertension, kidney stones, and possibly osteoporosis. However, currently there is insufficient evidence to establish a causal relationship between potassium intakes and the risk of these chronic conditions (10). As a consequence, median potassium intakes observed in apparently healthy people were used to set adequate intakes (AI) by age/life stage in the recent revision of the Dietary Reference Intakes (DRIs) for potassium. The revised AI values are 2.6 g/day for women and 3.4 g/day for men (see The Adequate Intake).

Fruit and vegetables are among the richest sources of dietary potassium, and a large body of evidence supports the association of increased fruit and vegetable intakes with reduced risk of cardiovascular disease (see the article on Fruit and Vegetables). The Linus Pauling Institute recommends the consumption of a diet high in potassium-rich foods (see Sources), especially fruit, vegetables, nuts, and dairy products to ensure adequate potassium intakes.

Older adults (>50 years)

A diet rich in fruit and vegetables that supplies 2.6-3.4 g/day of potassium (see AI) should contribute to maintaining a low risk of chronic disease in generally healthy older adults. This recommendation does not apply to individuals who have been advised to limit potassium consumption by a health care professional (see Safety).

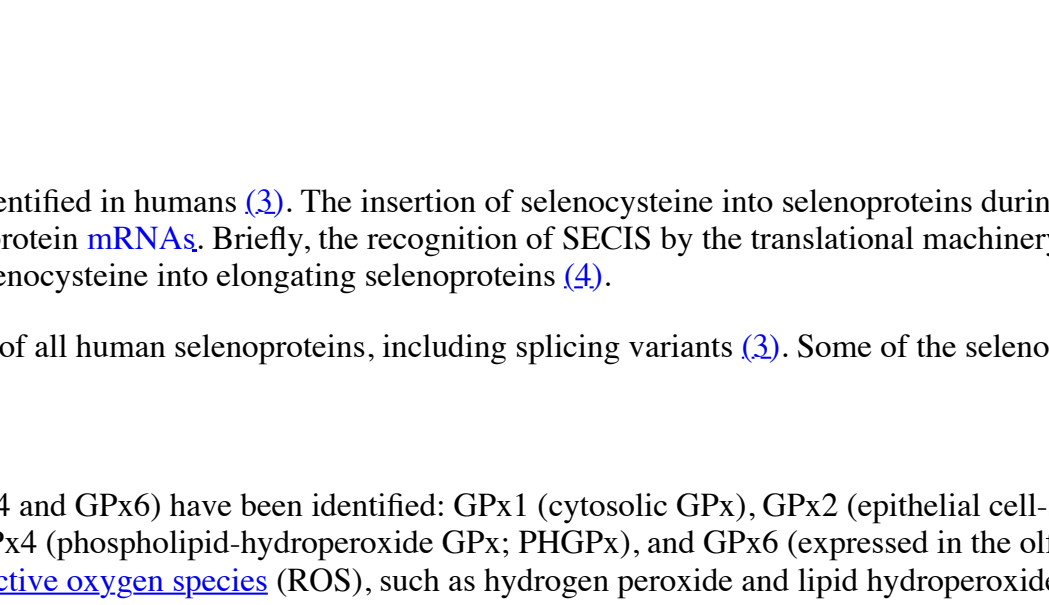
Summary

- Selenium exerts various biological functions mainly as part of the amino acid, selenocysteine, which is found in at least 25 selenocysteine-containing proteins (selenoproteins). *(More information)*
- Five glutathione peroxidases, three thioredoxin reductases, three iodothyronine deiodinases, and one methionine sulfoxide reductase B1 are among the best characterized selenoproteins with known functions. *(More information)*
- Impaired antioxidant protection in selenium-deficient individuals may affect physiological responses to stress. Keshan cardiomyopathy and Kashin-Beck osteoarthropathy are diseases occurring specifically in areas of selenium deficiency in Asia. *(More information)*
- The current recommended dietary allowance (RDA) set by the US Institute of Medicine is 55 μg/day for adolescents and adults of all ages. *(More information)*
- Early observational studies have found either null or inverse associations between selenium exposure and risk of site-specific cancers. However, current evidence from intervention trials in selenium-replete participants does not support a protective effect of selenium supplementation against cancer. *(More information)*
- Preliminary evidence from randomized controlled trials suggests that selenium supplementation may prevent viral load progression and increase immune cell count in HIV-positive patients. *(More information)*
- The levels and chemical forms of selenium in plant-based food vary according to the composition and selenium content of soil in which the plants are grown. Selenium-rich food sources include Brazil nuts, grains, seafood, organ meats, poultry, and dairy products. *(More information)*
- The tolerable upper intake level (UL) for selenium is 400 μg/day for adolescents and adults and includes both selenium obtained from food, which averages about 100 μg/day for adults in the US, and selenium from supplements. *(More information)*
- Because some evidence suggests that high serum selenium concentrations may have adverse effects on glycemic control, individuals with high selenium status and/or those at risk for type 2 diabetes mellitus should avoid taking selenium supplements. *(More information)*

Selenium is a trace element that is essential in small amounts, but like all essential elements, selenium can be toxic at high levels. Unlike plants, most animals — including humans — require selenium for the appropriate functioning of a number of selenium-dependent enzymes known as selenoproteins. During protein synthesis (translation), the amino acid selenocysteine is incorporated into elongating proteins at very specific locations in the amino acid sequence in order to form functional selenoproteins. Although higher plants do not appear to require selenium for survival, they can incorporate it non-specifically into sulfur-containing molecules when the mineral is present in the soil (1). Of note, in animals, the amino acid selenomethionine can be nonspecifically incorporated into proteins in place of methionine (2). However, only selenocysteine-containing proteins are regarded as selenoproteins (**Figure 1**).

Figure 1. Cysteine, Methionine, and Selenium-containing Analogs



Twenty-five human genes code for selenocysteine (Sec)-containing proteins known as selenoproteins. The incorporation of the amino acid Sec into proteins during translation is controlled by a regulatory element (named SECIS) in the 3'-untranslated region of mRNAs coding for selenoproteins. During translation, the recoding of the codon UGA as a signal to insert a Sec (rather than as a "stop codon") into elongating proteins requires the recognition of the SECIS sequence and the presence of a specific Sec-tRNA. Selenomethionine (Se-Met)-containing proteins are not selenoproteins per se. While the incorporation of Sec into selenoproteins is regulated and essential for proper folding and specific selenoprotein functions, the substitution of methionine (Met) with Se-Met is a nonspecific mechanism that does not result in structural and/or functional changes in proteins.

Function

Selenoproteins

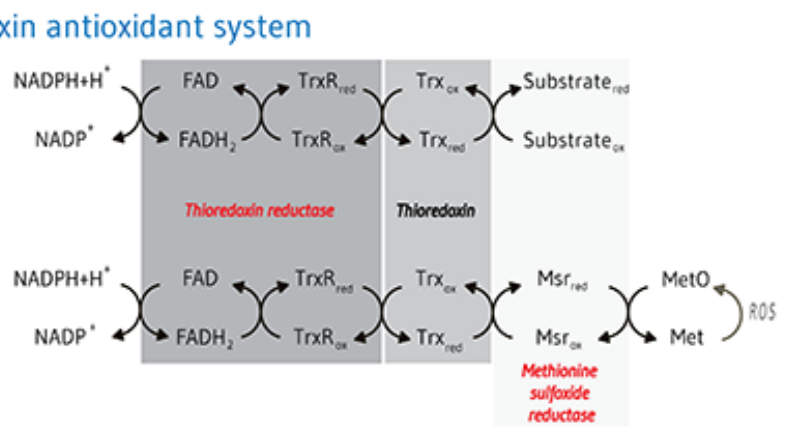
Twenty-five genes coding for selenoproteins have been identified in humans (3). The insertion of selenocysteine into selenoproteins during translation is directed by the presence of a selenocysteine-insertion sequence (SECIS) within selenoprotein mRNAs. Briefly, the recognition of SECIS by the translational machinery results in the recruitment of specific translational factors that decode in-frame UGA codons by inserting selenocysteine into elongating selenoproteins (4).

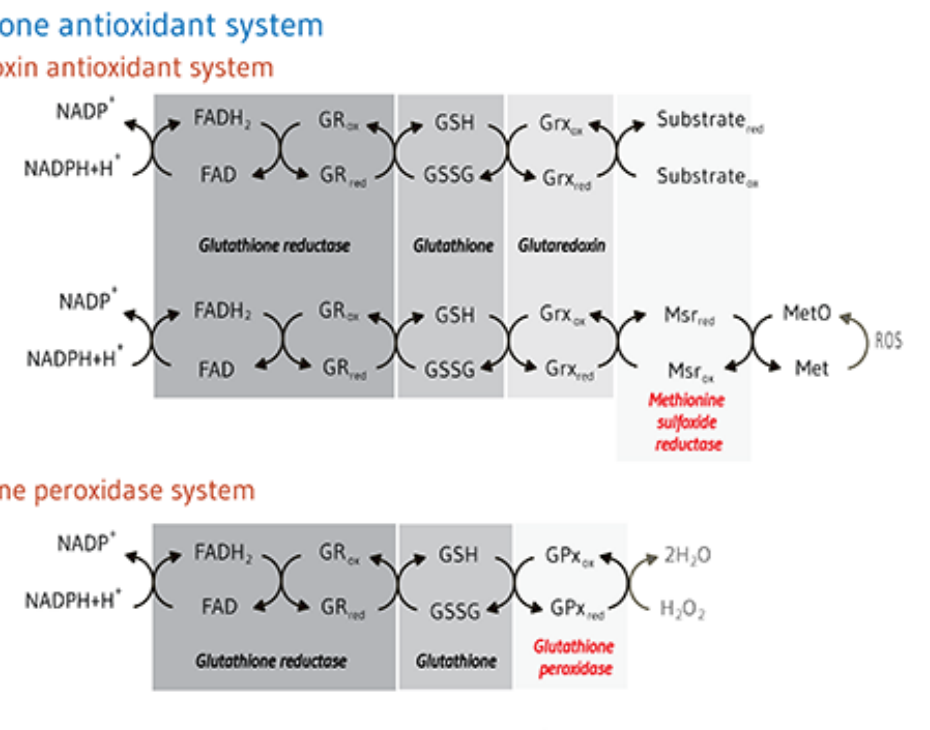
Research is gradually uncovering the metabolic functions of all human selenoproteins, including splicing variants (3). Some of the selenoproteins with an identified function include:

Glutathione peroxidases

Five selenium-containing glutathione peroxidases (GPx1-4 and GPx6) have been identified: GPx1 (cytosolic GPx), GPx2 (epithelial cell-specific GPx expressed in intestinal lining and lungs), GPx3 (highly expressed in thyroid gland and kidneys), GPx4 (phospholipid-hydroperoxide GPx; PHGPx), and GPx6 (expressed in the olfactory epithelium) (4). GPx isoenzymes are all antioxidant enzymes that reduce potentially damaging reactive oxygen species (ROS), such as hydrogen peroxide and lipid hydroperoxides, to harmless products like water and alcohols by coupling their reduction with the oxidation of glutathione (**Figure 2**). Spermatogenesis and male fertility are highly dependent on GPx4 and selenoprotein P (SEPP1; see below). In the testes, GPx4 reduces phospholipid hydroperoxides, hence protecting immature spermatozoa cells against oxidative stress. GPx4 is also a major structural protein of the capsule embedding mature sperm mitochondrial helix involved in sperm motility. SEPP1 is essential for selenium supply to the testes, and animal models lacking the *SEPP1* gene are infertile due to poor selenium tissue bioavailability, defective GPx4 synthesis, and impaired sperm maturation (5).

Figure 2. Selenoproteins in Thiol-based Antioxidant Systems





Selenoproteins (in red) are involved in two major thiol/disulfide-based antioxidant systems: (a) the thioredoxin (Trx) and (b) the glutathione (GSH) antioxidant systems. (a) Substrate reduction by the Trx system results from the transfer of electrons from NADPH to thioredoxin (Trx) via the selenoprotein thioredoxin reductase (TrxR). The family of methionine sulfoxide reductases (Msrs), which includes the selenoenzyme MsrB1 and catalyzes the reduction of methionine sulfoxide (MetO) to methionine (Met), can be readily reduced by both Trx and glutaredoxin (Grx) systems. (b) In the Grx system, electrons are transferred from NADPH to Grx via GSH reductase and GSH. Among the many substrates of the GSH-based redox system is the family of glutathione peroxidases (some of them are selenoenzymes) that can catalyze the conversion of hydrogen peroxide (H_2O_2) to water. *FAD, flavin adenine dinucleotide; GPx, GSH peroxidase; GR, GSH reductase; GSH, glutathione; GSSG, oxidized GSH; Grx, glutaredoxin; H_2O_2, hydrogen peroxide; Met, methionine; MetO, methionine sulfoxide; Msr, methionine sulfoxide reductase; NADP, phosphorylated nicotinamide adenine dinucleotide; ox, oxidized form; red, reduced form; ROS, reactive oxygen species; TrxR, thioredoxin reductase; Trx, thioredoxin.*

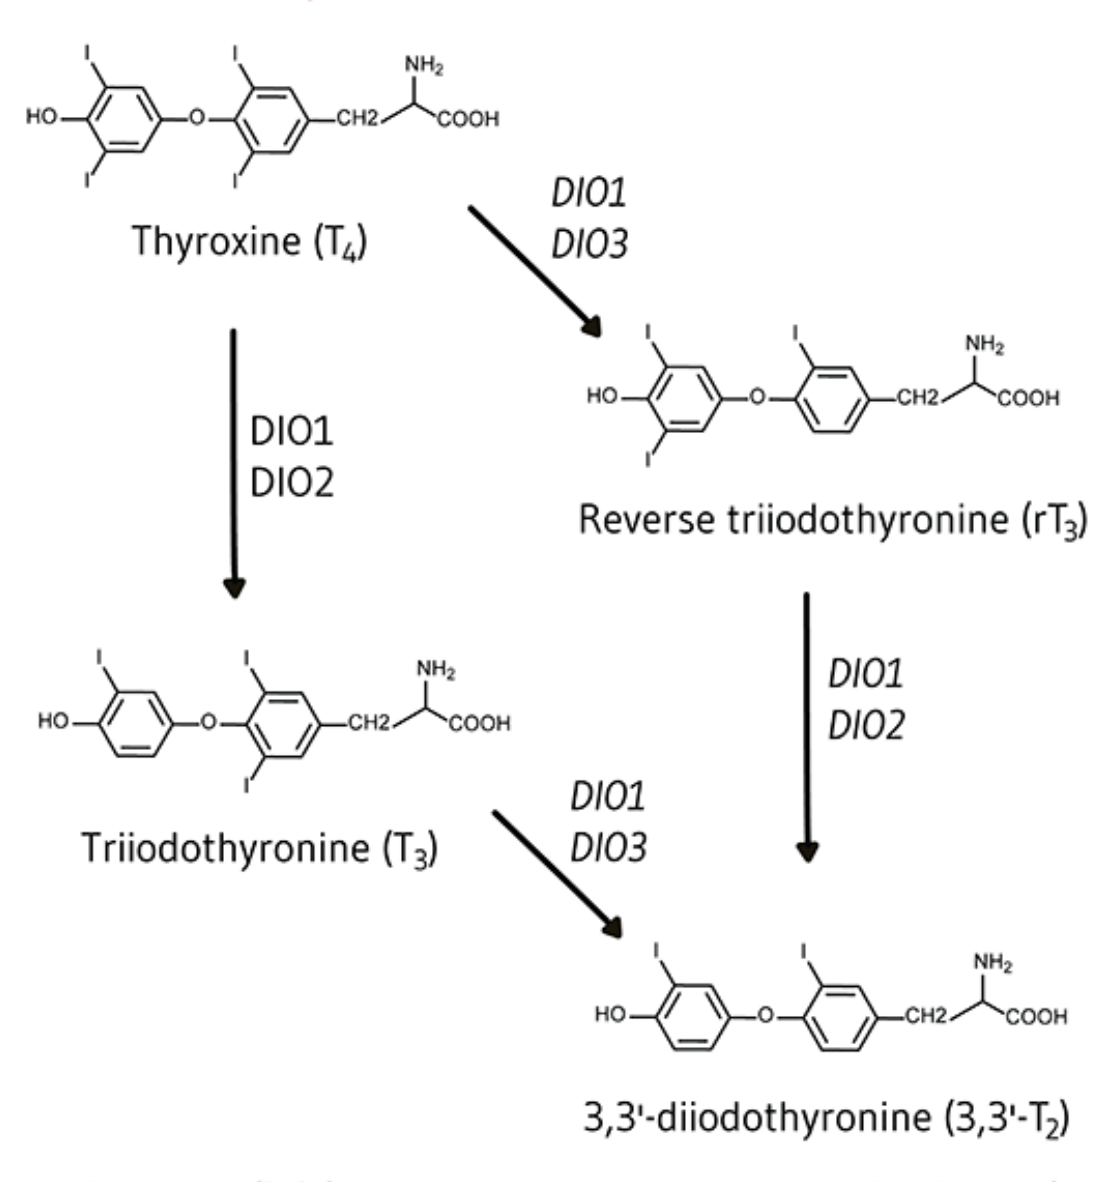
Thioredoxin reductases

In mammals, three selenocysteine-containing thioredoxin reductase (TrxR) isoenzymes have been identified in the thioredoxin system: cytosolic TrxR1, mitochondrial TrxR3, and testes-specific thioredoxin glutathione reductase TGR. TrxRs are homodimeric enzymes, and each monomer contains FAD- and NADPH-binding domains and a selenocysteine-containing catalytic site. TrxRs catalyze the reduction of a wide range of substrates, including thioredoxin and protein disulfide isomerase (PDI) (see **Figure 2** above). TrxRs also serve as electron donors for the regeneration of small antioxidants, possibly recycling ascorbic acid (vitamin C), α-lipoic acid, α-tocopherol (vitamin E), and coenzyme Q_{10} from their oxidized forms (6). The maintenance of thioredoxin in a reduced form by TrxRs is important for regulating cell growth and survival. The protein thioredoxin, together with TrxR1 (or TrxR3), NADPH, and FAD, constitute the thioredoxin antioxidant system involved in the reduction of antioxidant enzymes (e.g., peroxiredoxins, methionine sulfoxide reductases, and ribonucleotide reductase) and of many oxidation/reduction (redox)-sensitive signaling proteins (7). TrxR1 is one of the most investigated selenoproteins and regarded as one of the major antioxidant enzymes and redox regulators in mammalian cells.

Iodothyronine deiodinases (thyroid hormone deiodinases)

The thyroid gland releases very small amounts of biologically active thyroid hormone (triiodothyronine or T_3) and larger amounts of an inactive form of thyroid hormone (T_3 precursor: thyroxine or T_4) into the circulation. Most of the biologically active T_3 in the circulation and inside cells is generated by the removal of one iodine atom from T_4 in a reaction catalyzed by selenium-dependent iodothyronine deiodinase enzymes. Two different selenium-dependent iodothyronine deiodinases (DIOs type 1 and 2) can deiodinate T_4, thus increasing circulating T_3, while a third iodothyronine deiodinase (DIO type 3) can convert both T_3 and T_4 to inactive metabolites (**Figure 3**) (8). Of note, inactivation of the genes encoding DIOs in rodent models has revealed a role for DIO type 1 in iodine homeostasis and the importance of DIOs type 2 and 3 in the maturation of auditory and visual systems during fetal development (8). Thus the importance of selenium in normal development, growth, and metabolism is not limited to its role in the regulation of thyroid gland function.

Figure 3. Deiodination of Thyroid Hormones



Iodothyronine deiodinases (DIOs) are selenoenzymes that catalyze the deiodination (removal of iodine) from iodothyronines. Specifically, DIO1 and DIO2 catalyze the deiodination of thyroxine (T_4) that generates the biologically active triiodothyronine (T_3). DIO3 inactivates T_3 and T_4 by removing iodine atoms from the inner ring.

Selenoprotein P

Selenoprotein P (SEPP1) is predominantly produced by the liver, a major storage site for selenium, and secreted in the plasma. The full-length glycoprotein contains a selenium-rich domain with nine selenocysteine residues, as well as a thioredoxin-like catalytic site with one selenocysteine residue. SEPP1 constitutes the major form of selenium transport to peripheral tissues (9). SEPP1 also functions as an antioxidant that protects cells from oxidative damage by enabling full activity of thioredoxin reductases and glutathione peroxidases through adequate supply of selenium to extrahepatic tissues (see Glutathione peroxidases). SEPP1 appears to be especially critical for selenium homeostasis in the brain and testes where apolipoprotein E receptor 2 (apoER2) facilitates the uptake of SEPP1. Megalin is another SEPP1-specific lipoprotein receptor that helps limit urinary selenium loss through SEPP1 re-uptake by the kidneys (10). Moreover, SEPP1 has been recently implicated in the regulation of glucose metabolism and insulin sensitivity (11).

Selenoprotein W

Selenoprotein W (SEPW or SelW) exists in different isoforms (homologues) and is highly conserved across species. In humans, SEPW is expressed in numerous tissues, with highest levels found in skeletal muscle and heart (12). SEPW contains a selenocysteine residue and a cysteine residue that binds to a glutathione molecule, suggesting a role in redox regulation (13). The expression of SEPW is correlated with selenium status and appears to be sensitive to low-selenium supply (14, 15). SEPW expression in the brain has been found to confer protection against oxidative stress-induced neuronal cell death (16). SEPW also appears to be a negative regulator for 14-3-3 proteins. Indeed, 14-3-3 inhibition by SEPW in breast cancer cells was found to increase cell proliferation and cell survival through increasing resistance to genotoxic stress (17). In skeletal muscle cells, SEPW was shown to reduce the binding of 14-3-3 to TAZ, allowing TAZ translocation to the nucleus and subsequent activation of muscle cell differentiation genes (18). Finally, SEPW was found to prevent the degradation of the epidermal growth factor receptor (EGFR) in breast and prostate epithelial cells in culture. EGFR is constitutively activated in many tumors, and evidence of a role for SEPW in EGFR activation and signaling may help shed light on the relationship between selenium status and cancer risk (19).

Selenophosphate synthetase 2

There is no free pool of the amino acid selenocysteine in cells such that selenocysteine synthesis takes place on a specialized tRNA during the translation of selenoprotein mRNAs. The reaction is catalyzed by pyridoxal 5'-phosphate (PLP)-dependent L-seryl-tRNA^{Sec} selenium transferase and uses selenophosphate (monoselenium phosphate) as the selenium donor (**Figure 4**) (20). Selenophosphate synthetase 2 is a selenoenzyme that catalyzes the ATP-dependent synthesis of selenophosphate from hydrogen selenide (**Figure 4**) (3).

selenocysteine incorporation into elongating selenoproteins

Selenocysteine (Sec) synthesis takes place on a special tRNA initially aminoacetylated (charged) with the amino acid serine (Ser). Ser-tRNA$^{[Ser]Sec}$ is then phosphorylated to produce pSer-tRNA$^{[Ser]Sec}$. Pyridoxal 5'-phosphate (PLP)-dependent L-seryl-tRNA^{Sec} selenium transferase catalyzes the conversion of Ser-tRNA$^{[Ser]Sec}$ into Sec-tRNA$^{[Ser]Sec}$ using selenophosphate as selenium donor. Selenophosphate is synthesized from hydrogen selenide in a reaction catalyzed by the selenoenzyme selenophosphate synthetase 2. Selenocysteine is incorporated into elongating proteins during translation. *Se, selenium; Ser-tRNA, L-seryl-tRNA; Sec-tRNA, L-selenocysteinyl-tRNA.*

Methionine-R-sulfoxide reductase B1 (formerly selenoprotein R)

The methionine sulfoxide reduction system is involved in the protection against oxidative stress and is especially critical for the regeneration of proteins damaged by reactive oxygen species (ROS). Indeed, ROS can oxidize methionine residues (methionine sulfoxides) within proteins and potentially impair their activities. In humans, two stereospecific families of methionine sulfoxide reductases (MsrA and MsrB) are encoded by a single *MSRA* gene and three *MSRB* genes (*MSRB1-3*). MsrA catalyzes the reduction of the S-form of methionine sulfoxide; the R-form of methionine sulfoxide is reduced by MsrB1, 2, or 3. Only MsrB1 has been characterized as a selenoprotein with one selenocysteine residue in its catalytic site. MsrB1 appears to be involved in the redox regulation of certain proteins. In macrophages, reorganization of the actin cytoskeleton necessary for chemotaxis and phagocytosis requires MsrB1-dependent reduction of methionine-R-sulfoxide residues within actin (21). Studies using *MSR* gene inactivation in mice have also shown that methionine sulfoxide reduction is implicated in the regulation of the methionine cycle (reviewed in 22). Both the thioredoxin (Trx) and GSH-dependent glutaredoxin (Grx) antioxidant systems have been found to reduce methionine sulfoxide reductases *in vitro* and/or *in vivo* (see **Figure 2** above) (22).

15 kDa selenoprotein

15 kDa selenoprotein (selenoprotein 15; SEP15) is highly expressed in several tissues, including prostate, kidney, testes, liver, and brain (23). Although its function is not known, SEP15 was found to interact with the endoplasmic reticulum UDP-glucose:glycoprotein glucosyltransferase (UGGT), an enzyme involved in the quality control of glycoprotein folding (24, 25). Because SEP15 has a thioredoxin-like catalytic site, SEP15 is thought to either regulate UGGT activity or the redox state of UGGT substrates (26). Mice lacking a functional SEP15 were found to develop nuclear cataract (lens opacification) at a very early age suggesting that SEP15 may be critical to the quality control system of protein folding in the lens (27). SEP15 may also be implicated in anticancer mechanisms (reviewed in 28).

Selenoprotein S

The mammalian selenoprotein S (known as SEPS1, SelS, or VCP-interacting membrane selenoprotein [VIMP]) is an endoplasmic reticulum (ER) membrane protein. SEPS1 is involved in the cellular response to ER stress (ER-associated degradation; ERAD) activated by the detection of misfolded proteins. SEPS1 contributes to the removal and transfer (retrotranslocation) of misfolded proteins from the ER lumen to the cytosol where proteins are tagged with ubiquitin before being degraded. A polymorphism or variation in the sequence within an ER-response element located in the *SEPS1* promoter was found to result in reduced *SEPS1* promoter activity and gene expression (29). The polymorphism corresponding to the substitution of a guanine (G) by an adenine (A) at nucleotide -105 (-105G>A) has been associated with increased plasma levels of pro-inflammatory cytokines. In addition, a case-control study recently reported that the A allele was more prevalent in individuals affected by Hashimoto thyroiditis (HT) — a T-cell-mediated autoimmune disease resulting in the destruction of thyroid cells — than in healthy controls (30). Other associations between *SEPS1* polymorphism (including -105G>A) and susceptibility to various conditions, such as preeclampsia, coronary artery disease, or gastrointestinal cancers, strongly suggest a role for this selenoprotein in the regulation of inflammatory and immune responses (31-34).

Other less well-characterized selenoproteins, which are also localized in the ER lumen and/or membrane, include selenoproteins K, M, N, and T (35).

Nutrient interactions

Antioxidant nutrients

The importance of selenium to biological systems, and specifically to the cellular redox (pro-oxidant/antioxidant) balance, is derived from its presence as selenocysteine in the catalytic site of selenoproteins (see Function). Other minerals that are critical components of antioxidant enzymes include copper (as superoxide dismutase), zinc (as superoxide dismutase), and iron (as catalase). Selenium acts in synergy with the antioxidant vitamins, vitamin C (ascorbic acid) and vitamin E (α-tocopherol), by regenerating them from their oxidized forms and promoting maximal antioxidant protection (36-38).

Iodine

While iodine is an essential component of thyroid hormones, the selenium-containing iodothyronine deiodinases (DIOs) are enzymes required for the conversion of thyroxine (T_4) to the biologically active thyroid hormone, triiodothyronine (T_3) (see Function). DIO1 activity may also be involved in regulating iodine homeostasis (39). The selenoenzymes, glutathione peroxidases, also play a critical role in thyroid function because they catalyze the degradation of peroxides generated during thyroid hormone synthesis (8). The epidemiology of coexisting iodine and selenium deficiencies in central Africa, but not in China, has been linked to the prevalence of myxedematous cretinism, a severe form of congenital hypothyroidism accompanied by mental and physical retardation. Selenium deficiency may be only one of several undetermined factors that might exacerbate the detrimental effects of iodine deficiency (40). Interestingly, selenium deficiency in rodents was found to have little impact on DIO activities as it appears that selenium is being supplied in priority for adequate synthesis of DIOs at the expense of other selenoenzymes (8).

Deficiency

Insufficient selenium intake may negatively affect the activity of several selenium-responsive enzymes, including glutathione peroxidases (GPx1 and GPx3), iodothyronine deiodinases, selenoprotein W, and methionine-R-sulfoxide reductase B1 (MsrB1). Even when severe, isolated selenium deficiency does not usually result in obvious clinical illness. Yet, compared to subjects with adequate selenium status, selenium-deficient individuals might be more susceptible to additional physiological stresses (41). Prolonged selenium deficiency may likely contribute to Keshan and Kashin-Beck diseases (see below).

Individuals at increased risk of selenium deficiency

Selenium deficiency has been reported in chronically ill patients who were receiving total parenteral nutrition (TPN) without added selenium for prolonged periods of time. Muscular weakness, muscle wasting, and cardiomyopathy (inflammation and damage to the heart muscle) have been observed in these patients. Nowadays, TPN solutions are routinely supplemented with selenium. The risk of selenium deficiency may be increased following bariatric surgery or in severe gastrointestinal conditions, such as Crohn's disease. Some specialized medical diets like those used to treat certain metabolic disorders, including phenylketonuria, homocystinuria, and maple syrup urine disease, need to be supplemented with selenium to ensure optimum selenium status in patients (42).

Keshan disease

Keshan disease is a fatal form of dilated cardiomyopathy that was first described in young women and children in a selenium-deficient region in China. The acute form of the disease is characterized by the sudden onset of cardiac insufficiency, while the chronic form results in moderate-to-severe heart enlargement with varying degrees of cardiac insufficiency (43). The incidence of Keshan disease is closely associated with very low dietary intakes of selenium and poor selenium nutritional status. Selenium supplementation (in the form of sodium selenite; Na_2SeO_3) was found to protect people from developing Keshan disease but could not reverse heart muscle damage once it had occurred (43). A recent case-control study reported that selenium-responsive glutathione peroxidase 1 (GPx1) activity was significantly lower in Keshan patients compared to healthy individuals. Interestingly, a specific *GPX1* polymorphism resulting in a proline-to-leucine transition at position 198 (Pro198Leu) is associated with a reduction in GPx1 activity and found to be more prevalent in Keshan patients. This *GPX1* polymorphism might confer a greater susceptibility to Keshan disease in carriers with low selenium nutritional status (44).

While selenium deficiency is a major etiological factor of Keshan disease, the seasonal and annual variation in disease occurrence suggested that other factors, especially an infectious agent, might be involved in addition to selenium deficiency (45). Coxsackie virus B3 is one virus type that has been isolated from Keshan patients, and animal studies have shown that this virus was capable of causing an inflammation of the heart (myocarditis) in selenium-deficient mice. Studies in mice also indicated that oxidative stress induced by selenium deficiency could result in changes in the viral genome, such as to convert a relatively harmless strain of coxsackie virus B3 into a myocarditis-causing strain (43). Although not proven in Keshan disease, it is possible that selenium deficiency may increase the virulence of viruses with the potential to invade and damage the heart muscle (46).

Kashin-Beck disease

Kashin-Beck disease (KBD) is another endemic condition that affects an estimated 2.5 million people in Tibet, northern and central China, North Korea, and southeastern Siberia (47). KBD is characterized by the degeneration of articular cartilage between joints (osteoarthritis) that can result in joint deformities and dwarfism in the most severe forms of the disease. The disease affects children as young as two years old. As with Keshan disease, KBD is prevalent in selenium-deficient provinces and thus generally affects people with very low selenium intakes (47). Recent studies have suggested that increased susceptibility to KBD in selenium-deficient populations might result from a reduced antioxidant protection associated with polymorphisms in *GPX* genes (48, 49). Yet, the etiology appears to be multifactorial, as a number of other causative factors have been suggested for KBD, including fungal toxins in grain, iodine deficiency, and contaminated drinking water (43).

Recent meta-analyses of a few small trials and prospective cohort studies have indicated that improving selenium nutritional status in children living in endemic areas may help reduce KBD incidence (50). Also, there is limited evidence to suggest that selenium supplementation could be useful in the treatment of patients with KBD. A meta-analysis of 10 randomized controlled trials reported a significant increase in the repairing rate of bone lesions in KBD children supplemented with sodium selenite for at least one year (51). Larger trials of higher quality are needed to assess whether selenium supplementation could result in disease remission.

The Recommended Dietary Allowance (RDA)

The dietary reference intakes (DRIs) for selenium were last revised in 2000 by the Food and Nutrition Board (FNB) of the US Institute of Medicine. The most recent RDA is based on the estimated average requirement (EAR) needed to maximize antioxidant enzyme glutathione peroxidase (GPx) activity in plasma (52).

Table 1. Recommended Dietary Allowance (RDA) for Selenium

Life Stage	Age	Males (μg/day)	Females (μg/day)
Infants	0-6 months	15 (AI)	15 (AI)
Infants	7-12 months	20 (AI)	20 (AI)
Children	1-3 years	20	20
Children	4-8 years	30	30
Children	9-13 years	40	40
Adolescents	14-18 years	55	55
Adults	19 years and older	55	55
Pregnancy	all ages	-	60
Breast-feeding	all ages	-	70

Of note, the third National Health and Nutrition Examination Survey (NHANES III) reported that over 99% of the US participants had serum selenium concentrations consistent with selenium requirements being met (52), suggesting selenium supplementation is not needed for Americans.

Disease Prevention

Cancer

Animal studies

There has been considerable research on the effect of selenium supplementation on the incidence of cancer in animals. More than two-thirds of over 100 published studies in 20 different animal models of spontaneous, viral, and chemically induced cancers found that selenium supplementation (to at least adequate intake levels) significantly reduces tumor incidence, especially in comparison to selenium-deficient diets (53). Evidence of cancer-inhibiting effects of selenium has provided a strong rationale for investigating potential associations between selenium intake and cancer risk in humans.

Observational studies

Most of the early epidemiological evidence from case-control and nested case-control studies suggested either null or inverse associations between selenium exposure and risk of site-specific cancers (54). Markers of selenium exposure include toenail and blood selenium content, as well as plasma glutathione peroxidase (GPx) activity. However, it is not clear whether they adequately reflect selenium exposure from dietary and supplemental sources (see Sources) or selenium distribution in tissues and organs that may be affected by cancer. In the Danish Prospective Diet, Cancer, and Health prospective study that followed over 57,000 men and women for 14 years, the risk of rectal cancer was found to be 42% higher in current smokers compared to nonsmokers. No difference between smokers and nonsmokers regarding supplemental and dietary intakes of antioxidant micronutrients, including selenium, was found to contribute to the association of smoking and rectal cancer (55). Yet, because studies have consistently reported lower blood selenium concentrations and GPx activities in smokers compared to nonsmokers (reviewed in 56), estimation of selenium intakes might not be a reliable marker of selenium exposure in this population. Also, the chemical forms of selenium found in food are varied (see Sources) and may have very different biological and toxicological effects (57, 58).

A recent Cochrane review included 55 completed observational studies — mostly with a nested case-control design — published over three decades (54). A meta-analysis of 16 of these observational studies, including over 144,000 individuals, reported that higher versus lower selenium status was associated with a 31% lower risk of cancer at any site and a 40% lower risk of cancer-related mortality. A significantly lower risk was reported for bladder cancer (5 studies) and prostate cancer (17 studies); however, higher selenium status was not inversely associated with risks of breast cancer (8 studies), lung cancer (12 studies), colorectal cancer (5 studies), and gastric cancer (5 studies) (54). Another meta-analysis of 16 observational studies reported an inverse relationship between breast cancer and serum selenium concentrations (59). Gender differences in cancer susceptibility have been reported in some studies, although consistent evidence of different effects in men and women appears to be lacking.

Single nucleotide variations (polymorphisms) in the sequence of genes can modify gene expression level and the stability and activity of the synthesized proteins. For example, a proline-to-leucine transition caused by a specific polymorphism in the *GPX1* gene (rs1050450 C>T) is associated with reduced GPx1 enzymatic activity. The description of several polymorphisms in genes encoding selenoproteins has led to evaluation of possible associations with selenium status and cancer incidence. Notably, certain polymorphisms in genes coding for selenoproteins have been associated with increased risks of gastric and colorectal cancers (reviewed in 60). Additionally, a number of studies have investigated the effect of selenoprotein polymorphisms on the relationship between selenium status and prostate cancer risk. A nested case-control study within the EPIC-Heidelberg cohort has combined genotyping for several selenoprotein variants with markers of selenium status (61). Briefly, the study showed that a *GPX1* gene polymorphism (rs1050450 C>T) affected the association between selenium concentrations and prostate cancer risk. Specifically, selenium concentrations were found to be inversely associated with prostate cancer risk only among carriers of the *GPX1 T* allele. Additional variants in selenoprotein genes may mitigate the effect of selenium status on the risk of prostate cancer (62, 63). In another nested case-control study within the Physicians' Health Study (PHS), individuals in the highest versus lowest quartile of selenium concentrations were found to have a reduced risk of prostate cancer-related mortality except if carrying a specific variant in 15kDa selenoprotein gene (*SEP15* rs561104 G>A) (64). More research is needed to further unravel the mechanisms underlying the influence of gene-diet interactions on the risk of developing cancer.

Intervention trials

Community-based studies: A very early intervention study of selenium supplementation was undertaken in China among a general population of 130,471 individuals living in a high-risk area for viral hepatitis B infection and liver cancer. The trial provided table salt enriched with sodium selenite to the population of one township (20,847 people) using four other townships as controls. During an eight-year follow-up period, the average incidence of liver cancer was reduced by 35% in the selenium-supplemented population, while no reduction was found in the control populations. In a clinical trial in the same region, 226 individuals with evidence of chronic hepatitis B infection were supplemented daily with either 200 μg of selenium in the form of a selenium-enriched yeast tablet or a placebo yeast tablet. During the 4-year follow-up period, 7 out of 113 individuals on the placebo developed primary liver cancer, while none of the 113 subjects supplemented with selenium developed liver cancer (65).

Randomized controlled trials: The double-blind, placebo-controlled Nutritional Prevention of Cancer (NPC) study in 1,312 older adults with a history of nonmelanoma skin cancer found that supplementation with 200 μg/day of selenium-enriched yeast (selenized yeast) for an average of 7.4 years resulted in a 52% decrease in prostate cancer incidence in men (reviewed in 66). The protective effect of selenium supplementation was greatest in men with lower baseline plasma selenium and prostate-specific antigen (PSA) levels. A reduced incidence in lung, colorectal, and total cancer was also associated with supplementation with 200 μg/day (67) but not with 400 μg/day of selenium-enriched yeast (68). Besides, selenium supplementation increased the risk of one type of skin cancer (squamous cell carcinoma) by 25%. A larger randomized, placebo-controlled intervention trial (the SELECT study) in more than 35,000 middle-aged and selenium-replete men, randomized to receive selenium (in the form of selenomethionine, 200 μg/day) and/or vitamin E supplementation, was halted because of concerns regarding an increased risk of type 2 diabetes with selenium and increased risk of prostate cancer with vitamin E (69, 70). In addition, the supplementation of selenium, alone or together with vitamin E, did not show any benefits regarding the risk of prostate, lung, or colorectal cancers after 5.5 years of follow-up (71, 72). Outcomes from other smaller trials (reviewed in 66) also suggested either a lack of an effect or the possibility of an increased risk of cancer. The lack of a beneficial effect of selenium supplementation was supported in a recent meta-analysis of randomized controlled trials (54).

Cardiovascular disease

Low activity levels of the selenoenzymes, glutathione peroxidases (GPx), have been reported in oxidative stress-related diseases, including cardiovascular disease (CVD) (73). Theoretically, the maintenance of an optimal selenium status has the potential to protect against oxidative stress (including lipid peroxidation) and could eventually prevent chronic inflammation and cardiovascular disorders. Yet, analyses of cross-sectional data from 13,887 US adults included in the Third National Health and Nutrition Examination Survey (NHANES III, 1988-1994) failed to show any significant associations between serum selenium concentrations and mortality from CVD, coronary artery/heart disease (CAD), or stroke (74). In addition, while individuals with renal insufficiency are at higher risk of developing CAD compared to those with normal kidney function, that risk was not found to be greater with low rather than normal selenium concentrations in serum (≤98 ng/mL vs. >98 ng/mL) (75).

A cross-sectional study based on NHANES 2003-2004 data from 2,638 participants ages 40 years and over found that the risk of high blood pressure (hypertension), a major contributing factor for CVD, was 73% higher in individuals in the upper versus lowest quintile of serum selenium concentrations (≥150 ng/mL vs. <122 ng/mL) (76). Yet, a recent systematic review of the literature failed to find enough evidence to support any relationship between serum selenium concentrations and hypertension (77). Besides, a few observational studies have also reported associations between normal-to-high selenium status and elevated serum lipid levels in selenium-replete populations, speculating that selenium might interfere with lipid metabolism and adversely affect cardiovascular health (78, 79). At present, randomized controlled trials have not provided consistent results regarding the effect of selenium supplementation on lipid levels nor have they demonstrated any additional cardiovascular benefits of selenium in individuals with suboptimal or optimal selenium intakes (80).

Disease Treatment

Immune dysfunction

Selenium deficiency has been associated with impaired immunity and chronic inflammation (81). A considerable amount of research conducted in cell culture and animal models indicates that selenium plays essential roles in regulating the migration, proliferation, differentiation, activation, and optimal function of immune cells, thus influencing innate immunity, B-cell dependent antibody production, and T-cell immunity (reviewed in 82). Recent evidence on the role of selenium and selenoproteins in the production of lipid mediators (called eicosanoids) involved in inflammatory responses suggests that selenium supplementation might mitigate dysfunctional inflammatory responses that contribute to the pathogenesis of many chronic health conditions (83). At present, randomized controlled trials are needed to evaluate the potential benefits of selenium supplementation in inflammatory disorders, such as asthma (84) and inflammatory bowel disease (85).

Infectious diseases

HIV/AIDS

In areas of widespread malnutrition, deficiencies in micronutrients (including selenium) are common in individuals infected by the human immunodeficiency virus (HIV) that causes acquired immunodeficiency syndrome (AIDS). Before antiretroviral therapy (ART) became the standard for HIV treatment, observational studies had consistently reported associations between low serum selenium concentrations and HIV infection in well-nourished subjects (86). Poor selenium status has been linked to increased risks of dilated cardiomyopathy and mortality in HIV-infected children and adults, as well as mother-to-child HIV transmission and perinatal mortality (reviewed in 87. Early laboratory studies have suggested that HIV might disrupt normal antioxidant defenses in infected T-cells by reducing the levels of selenoproteins, i.e., thioredoxine reductases and glutathione peroxidases (87). Interestingly, a recent cross-sectional study found that HIV-seropositive individuals receiving ART for more than two years had undetectable plasma viral loads, higher CD4 lymphocyte T-cell counts, and adequate serum selenium concentrations compared to ART-naïve subjects (88). Because the antioxidant activity of selenoproteins may interfere with viral replication in HIV-infected immune cells (89,90), it has been suggested that selenium supplementation might serve as a potential adjunct to ART for HIV patients.

A few trials of selenium supplementation in HIV-infected individuals have been conducted. A randomized, double-blind, placebo-controlled trial in 186 HIV-positive adults initially found that selenium supplementation at 200 μg/day for two years significantly decreased the rate of hospital admissions (91). Another randomized, double-blind, placebo-controlled trial in 174 HIV-positive individuals reported that 200 μg/day of selenium supplementation (in the form of selenium-enriched yeast) for nine months increased serum selenium concentrations, improved CD4 lymphocyte T-cell count, and prevented any progression of the HIV viral load (92). In a third double-blind trial in Tanzania, 913 pregnant women between 12 and 27 weeks' gestation were randomized to receive 200 μg/day of selenium (as selenomethionine) or a placebo until six months after birth. Selenium supplementation had no effect on maternal CD4, CD8, and CD3 T-cell counts and on HIV viral load, but it significantly decreased the risk of acute or persistent diarrhea (93, 94). In addition, the risk of death between six weeks and six months postpartum was significantly reduced in infants of mothers supplemented with selenium compared to placebo (94).

A recent four-armed trial in Botswana randomized 878 HIV-positive adults at an early stage of the infection to receive either a placebo treatment, multivitamins (vitamins B, C, and E), 200 μg/day of selenium, or both multivitamins and selenium for 24 months (95). Unlike selenium alone, supplementation with multivitamins (with or without selenium) reduced the risk of immune decline by significantly increasing the time before ART initiation became necessary (i.e., when CD4 T-cell count fell below 251 cells/mcL) compared to placebo. In the study, a combined outcome of (1) CD4 T-cell count falling below 251 cells/mcL; (2) occurrence of AIDS-defining conditions; and (3) AIDS-related death — whichever happened first — was used to evaluate disease progression in the different arms of treatment. Compared to placebo, there was a longer period of time from randomization to the date of the composite outcome in individuals supplemented with multivitamins plus selenium, but not in those who received multivitamins or selenium alone (95). More research is needed to replicate these preliminary results, especially in settings and communities where malnutrition hastens the progression of HIV infection and access to antiretroviral therapy may be limited.

Sepsis

The systemic inflammatory response syndrome (SIRS) results from a systemic inflammatory response that can be due to an infection (sepsis) (96). Severe sepsis and septic shock — defined as persistent sepsis-induced low blood pressure — are associated with elevated mortality rates in critically ill patients (96, 97). Because systemic inflammatory responses involve excessive oxidative stress, it has been suggested that providing antioxidant nutrients like selenium may improve the outcome of critically ill patients in intensive care units. Two recent meta-analyses of randomized controlled trials found that intravenous selenium supplementation (as sodium selenite) in critically ill patients with SIRS, sepsis, or septic shock resulted in significantly reducing the risk of mortality by 17% to 27% (98, 99). More trials are needed to identify the appropriate schedule of selenium administration (in terms of dose, route, and treatment duration) and to assess additional outcomes (e.g., infectious complications and length of hospital stay).

Autoimmune thyroid diseases

Hashimoto thyroiditis (HT; chronic autoimmune thyroiditis) is an autoimmune disease characterized by T-cell infiltration in the thyroid gland and circulating autoantibodies (predominantly raised against thyroid peroxidase), causing prolonged inflammation, tissue damage, and hypothyroidism (8). While the function of the thyroid gland of healthy individuals is usually protected from variations in selenium supply, selenium deficiency and genetic polymorphisms affecting the activity of selenoproteins might be potential contributing factors to autoimmune thyroid diseases. A recent systematic review (100) identified four randomized controlled trials that evaluated the effect of selenium supplementation as an adjunct treatment to T_4 replacement therapy (levothyroxine) in HT patients (101-104). While three out of four studies suggested a reduction in levels of circulating autoantibodies, none of them provided information on whether selenium may improve mood- and health-related symptoms to allow for a decreased dosage of levothyroxine. Another randomized controlled trial found that selenium supplementation improved the well being of patients affected by another autoimmune thyroid disease leading to hyperthyroidism (Graves disease) (105). The results of two ongoing, randomized, placebo-controlled trials — the CATALYST in HT patients and the GRASS trial in patients with Graves disease — may provide insight into an effect of selenium on thyroid-specific quality-of-life criteria and inform clinical decision making (106, 107).

Sources

Food sources

The richest food sources of selenium are organ meats and seafood, followed by muscle meats. Drinking water is not considered to be a significant source of selenium in North America. However, in areas, where high levels of selenium in soil contribute to the selenium content of the water, higher levels of selenium may be found in wells used for drinking water (108). In general, there is wide variation in the selenium content of plants and grains, especially because some plants, including garlic, Brazil nuts, and multiple *Brassica* species, tend to accumulate selenium ('selenium accumulators'), while other assimilate selenium to a lesser extent ('non-accumulators'). The assimilation of selenium by plants also depends on soil selenium content. Brazil nuts grown in areas of Brazil with selenium-rich soil may provide more than 100 μg of selenium in one nut, while those grown in selenium-poor soil provide 10 times less (109). In the US, grains are a good source of selenium, but fruit and vegetables tend to be relatively poor in selenium.

Various chemical forms (species) of selenium are found in selenium accumulators, including selenate (inorganic selenium), selenomethionine, selenocysteine, selenium-methyl-selenocysteine, and γ-glutamyl-selenium-methyl-selenocysteine. Although the two latter compounds are predominant in plants of the *Allium* and *Brassicaceae* families (which include garlic, onion, and broccoli), wheat, other grains (including Brazil nuts), and soy are rich in selenomethionine and contain smaller amounts of selenocysteine and selenate. Less is known about selenium species and distribution in dietary sources of animal origin. Animal nutrition and growth conditions certainly contribute to the selenium species formed and their relative quantities, and it is assumed that the metabolic pathway of dietary selenium in animals is similar to that in humans. Selenocysteine is predominantly formed in animals fed inorganic selenium, while selenomethionine is derived from dietary sources of plant origin (reviewed in 110).

In the US, the national survey NHANES III reported mean dietary intakes ranging between 100.5 μg/day and 158.5 μg/day in adults ages 19-50 years (52). **Table 2** lists some good food sources of selenium and their selenium content in micrograms (μg). For more information on the selenium content of specific foods, search USDA's FoodData Central.

Table 2. Some Common Food Sources of Selenium

Food	Serving	Selenium (μg)
Brazil nuts (from selenium-rich soil)	1 ounce (6 kernels)	543.5*
Tuna (yellowfin, cooked, dry heat)	3 ounces	92.0
Oysters (Pacific, raw)	3 ounces	65.4
Clams (mixed, cooked, steamed)	3 ounces	54.4
Halibut (Atlantic and Pacific, cooked, dry heat)	3 ounces	47.1
Shrimp (cooked, steamed)	3 ounces	42.1
Salmon (Chinook, cooked, dry heat)	3 ounces	39.8
Noodles (egg, cooked, enriched)	1 cup	38.2
Crab (queen, cooked, steamed)	3 ounces	37.7
Pork (lean, tenderloin, cooked, roasted)	3 ounces	32.5
Beef (lean, plate steak, cooked, grilled)	3 ounces	30.6
Chicken (light-meat, cooked, roasted)	3 ounces	25.8
Rice (brown, long-grain, cooked)	1 cup	19.1
Sunflowers seed kernels (dried)	¼ cup	18.6
Whole-wheat bread	2 slices	16.4
Milk (fat free or skim)	8 fluid ounces (1 cup)	7.6
*Above the tolerable upper intake level (UL) of 400 μg/day.		

Supplements

Selenium supplements are available in several forms. Sodium selenite and sodium selenate are inorganic forms of selenium. Sodium selenate is almost completely absorbed, but a significant amount is excreted in the urine before it can be incorporated into proteins. Sodium selenite is only about 50% absorbed but is better retained than selenate once it is absorbed. Selenomethionine is about 90% absorbed (52); however, only about 34% may then actually be converted to free selenomethionine (111). Selenomethionine and selenium-enriched yeast, which mainly supply selenomethionine, are also available as supplements. The consumer should be aware that some forms of selenium-enriched yeast on the market contain yeast plus mainly inorganic forms of selenium.

Although both inorganic and organic forms of selenium can be metabolized to selenocysteine by the body and incorporated into selenoenzymes, they may not equally contribute to the maintenance of an adequate selenium status. In intervention trials, supplementation with an organic form of selenium (selenomethionine) more effectively increased blood selenium concentrations compared to supplementation with inorganic forms (i.e., sodium selenite and sodium selenate) (110). Yet, inorganic forms may increase plasma glutathione peroxidase (GPx) activity more effectively than organic forms (reviewed in 112). It has also been suggested that the incorporation of selenomethionine in place of methionine into tissue proteins may ensure that selenium is available upon protein turnover (110).

Selenium-enriched foods

Selenium-enriched foods have been of interest to scientists, especially because of the suggestion that some of the chemical forms of selenium produced by plants might be more potent modifiers of cancer risk than those currently available in supplements. Although there is currently no evidence of long-term health benefits associated with the consumption of selenium-enriched foods, results from animal studies and intervention trials suggest that protein-based sources of selenium are more effective at increasing GPx activity than selenium-enriched yeast and selenomethionine (112). Food fortification may also represent a cost-effective strategy to improve selenium nutritional status in populations at risk of inadequacy (113).

Safety

Toxicity

Although selenium is required for health, high doses of selenium can be toxic. Acute and fatal toxicities have occurred with accidental or suicidal ingestion of gram quantities of selenium. Clinically significant selenium toxicity was reported in 13 individuals after taking supplements that contained 27.3 mg (27,300 μg) per tablet due to a manufacturing error. Chronic selenium toxicity (selenosis) may occur with smaller doses of selenium over long periods of time. The most frequently reported symptoms of selenosis are hair and nail brittleness and loss. Other symptoms may include gastrointestinal disturbances, skin rashes, a garlic breath odor, fatigue, irritability, and neurologic disorders. In an area of China with a high prevalence of selenosis, toxic effects occurred with increasing frequency when blood selenium concentrations reached a level corresponding to an intake of 850 μg/day.

The Food and Nutrition Board (FNB) of the US Institute of Medicine set the tolerable upper intake level (UL) for selenium at 400 μg/day in adults based on the prevention of hair and nail brittleness and loss and early signs of chronic selenium toxicity (52). The UL of 400 μg/day for adults includes both selenium obtained from food and selenium from supplements (**Table 3**).

Table 3. Tolerable Upper Intake Level (UL) for Selenium

Age Group	UL (μg/day)
Infants 0-6 months	45
Infants 6-12 months	60
Children 1-3 years	90
Children 4-8 years	150
Children 9-13 years	280
Adolescents 14-18 years	400
Adults 19 years and older	400

Do selenium supplements increase the risk for type 2 diabetes mellitus?

A few studies have examined the relationship between selenium status and type 2 diabetes mellitus. In the cross-sectional analysis of NHANES III (1988-1994) data from 8,876 adult participants, the highest versus lowest quintile of serum selenium concentrations (≥137 ng/mL vs. <111 ng/mL) was associated with an increased risk of type 2 diabetes (114). Data analyses from 917 participants (≥40 years of age) of NHANES 2003-2004 also indicated an increased prevalence of type 2 diabetes in the highest versus lowest quartile of serum selenium concentrations (≥147 ngm/L vs. <124 ng/mL). Individuals in the highest versus lowest quartile of serum selenium concentrations also had higher levels of plasma glucose and glycated hemoglobin, suggestive of poor glycemic control (115). The randomized, double-blind, placebo-controlled study in 1,312 participants in the Nutritional Prevention of Cancer (NPC) trial found that selenium supplementation (200 μg/day; mean follow-up of 7.7 years) significantly increased the risk for type 2 diabetes in participants in the highest tertile of baseline plasma selenium concentrations (116). In addition, in the Selenium and Vitamin E Cancer Prevention Trial (SELECT), more cases of type 2 diabetes were found in the selenium group (200 μg/day; median follow-up of 5.5 years) than in the placebo group, but this was only a trend and not statistically significant (72).

At present, the mechanisms behind these observations are not well understood. An increase in insulin sensitivity has been reported in individuals with congenital (inborn) deficiency of most selenoproteins (117). Results from several animal studies also indicated that selenium supplementation and selenoproteins may interfere with insulin action and glucose homeostasis (reviewed in 118). On the other hand, recent studies have found that impaired glucose metabolism in patients with type 2 diabetes may affect SEPP1 expression and selenium homeostasis (11, 119, 120). While more research is needed to fully understand the interplay between carbohydrate metabolism and selenium homeostasis, the use of selenium supplements is considered unlikely to increase the risk of type 2 diabetes in healthy individuals but should be discouraged in those with high selenium status and/or at increased risk for developing type 2 diabetes (118).

Drug interactions

At present, few interactions between selenium and medications have been reported (121). For example, the anticonvulsant drug valproic acid and the chemotherapeutic agent cisplatin may lower circulating selenium concentrations in treated subjects (122, 123). Also, supplemental sodium selenite was found to reduce the toxicity of the antibiotic nitrofurantoin and the herbicide paraquat in animal studies (124).

Antioxidant supplements and statins

A three-year randomized controlled trial in 160 patients with documented coronary artery disease (CAD) and low high-density-lipoprotein (HDL) levels found that a combination of simvastatin (Zocor) and niacin increased HDL2 subfraction levels, inhibited the progression of coronary artery stenosis (narrowing), and decreased the frequency of cardiovascular events (125). Surprisingly, when an antioxidant combination (1,000 mg of vitamin C, 800 IU of vitamin E (*d*-α-tocopherol), 100 μg of selenium, and 25 mg of β-carotene daily) was taken with the simvastatin-niacin combination, the protective effects were diminished. However, the individual contribution of selenium cannot be established, and other studies have reported that antioxidant vitamins alone could interfere with the action of HDL-raising drugs, including statins (126).

Linus Pauling Institute Recommendation

The average American diet is estimated to provide about 100 μg/day of selenium, an amount that is well above the current RDA (55 μg/day) and appears sufficient to optimize plasma and cellular glutathione peroxidase (GPx) activity. A recent 10-week randomized controlled study in healthy British adults (ages, 50-64 years) estimated that about 105 μg/day of total selenium intake was required to maximize the plasma concentrations of selenoprotein P (SEPP1), another useful biomarker of selenium status (127). However, a similar trial in an American cohort with higher baseline plasma selenium concentrations found no effect of selenium supplementation on SEPP1 concentrations (128). While the amount of selenium in multivitamin/mineral (MVM) supplements varies considerably, MVM supplements rarely provide more than the Daily Value (DV) of 70 μg. Eating a varied diet and taking a daily MVM supplement should provide sufficient selenium for most people in the US and help improve selenium status in populations with lower selenium intakes outside the US.

Men

At present, the effect of selenium supplementation on cancer risk is not clear enough to support a general recommendation for an extra selenium supplement, especially in men with serum selenium concentrations consistent with adequate selenium intakes. The SELECT trial found that 200 μg/day of selenium did not reduce the risk of prostate cancer (72), refuting the results of the NPC trial (see Cancer). Another recent multicenter, randomized, double-blind, placebo-controlled trial (the Negative Biopsy Trial) in 699 men at high risk of prostate cancer found no effect of either 200 μg/day or 400 μg/day of selenium on prostate cancer risk during a mean follow-up of 36 months (129). In addition, because current evidence suggests a U-shaped relationship between selenium status and prostate cancer risk (130), men should avoid taking supplemental selenium that would exceed 200 μg/day.

Women

At present, there is no clinical evidence showing that selenium supplementation above recommended levels decreases the risk of breast cancer although some, but not all, observational studies have found an inverse relationship between selenium status and breast cancer in women (59).

Older adults (>50 years)

Aging has not been associated with significant changes in the requirement for selenium. A five-year, randomized, double-blind, placebo-controlled trial in healthy Danish older people (ages at inclusion, 60-74 years) found that selenium supplementation (100-300 μg/day) had little-to-no impact on circulating levels of antioxidant enzymes, including GPx (131).

Summary

- Sodium and chloride — major electrolytes of the fluid compartment outside of cells (i.e., extracellular) — work together to control extracellular volume and blood pressure. Disturbances in sodium concentrations in the extracellular fluid are associated with disorders of water balance. *(More information)*
- Various mechanisms act on the kidney to ensure that the amount of sodium lost via renal excretion compensates adequately for the amount of sodium consumed, thereby maintaining sodium homeostasis. *(More information)*
- Hyponatremia (abnormally low sodium concentrations in blood) is common among older adults and in individuals with hypertension, kidney disease, and heart disease. Hyponatremia also occurs in up to 30% of hospitalized patients. *(More information)*
- Acute severe hyponatremia may lead to brain edema with neurologic consequences and be lethal if not promptly diagnosed and treated. Mild chronic hyponatremia with long-term adverse health effects, such as attention deficits, gait instability, falls, and bone loss and fractures, has been associated with cardiovascular morbidity and mortality. *(More information)*
- In 2019, the National Academy of Medicine established an adequate intake (AI) for sodium of 1.5 grams (g)/day in adults, equivalent to 3.8 g/day of sodium chloride (salt). *(More information)*
- The National Academy of Medicine established a Chronic Disease Risk Reduction Intake (CDRR) for sodium of 2.3 g/day (5.8 g/day of salt) for adults based on evidence of potential long-term health benefits on blood pressure and risk of hypertension and cardiovascular disease associated with reducing sodium intakes below this level. *(More information)*
- Current sodium intakes of the US adult population far exceed the CDRR. Sodium has been identified as a nutrient of public health concern for overconsumption. *(More information)*
- Excess dietary sodium is a major contributor to hypertension, which is a leading preventable risk factor for cardiovascular disease. Randomized controlled studies demonstrated that dietary sodium reduction (by 1.8 to 3.2 g/day) could lower blood pressure in subjects with elevated blood pressure. Yet, current evidence fails to support a decrease in cardiovascular morbidity and mortality with moderate sodium restriction in patients with hypertension. *(More information)*
- Additional adverse health outcomes, including gastric cancer, osteoporosis, and kidney stones, have also been linked to sodium overconsumption. *(More information)*

Salt (sodium chloride) is essential for life. Total body sodium in an average 70-kg person is of about 4,200 mmol (~100 g), of which 40% is found in bone and 60% in the fluid inside and outside of cells (1). Total body chloride averages 2,310 mmol (~82 g), of which 70% is distributed in the extracellular fluid and the remaining is found in the collagen of connective tissue (1). Multiple mechanisms work in concert to tightly regulate the body's sodium and chloride concentrations. Although this review emphasizes the function and requirements of sodium, sodium and chloride ions work together to control extracellular volume and blood pressure (1).

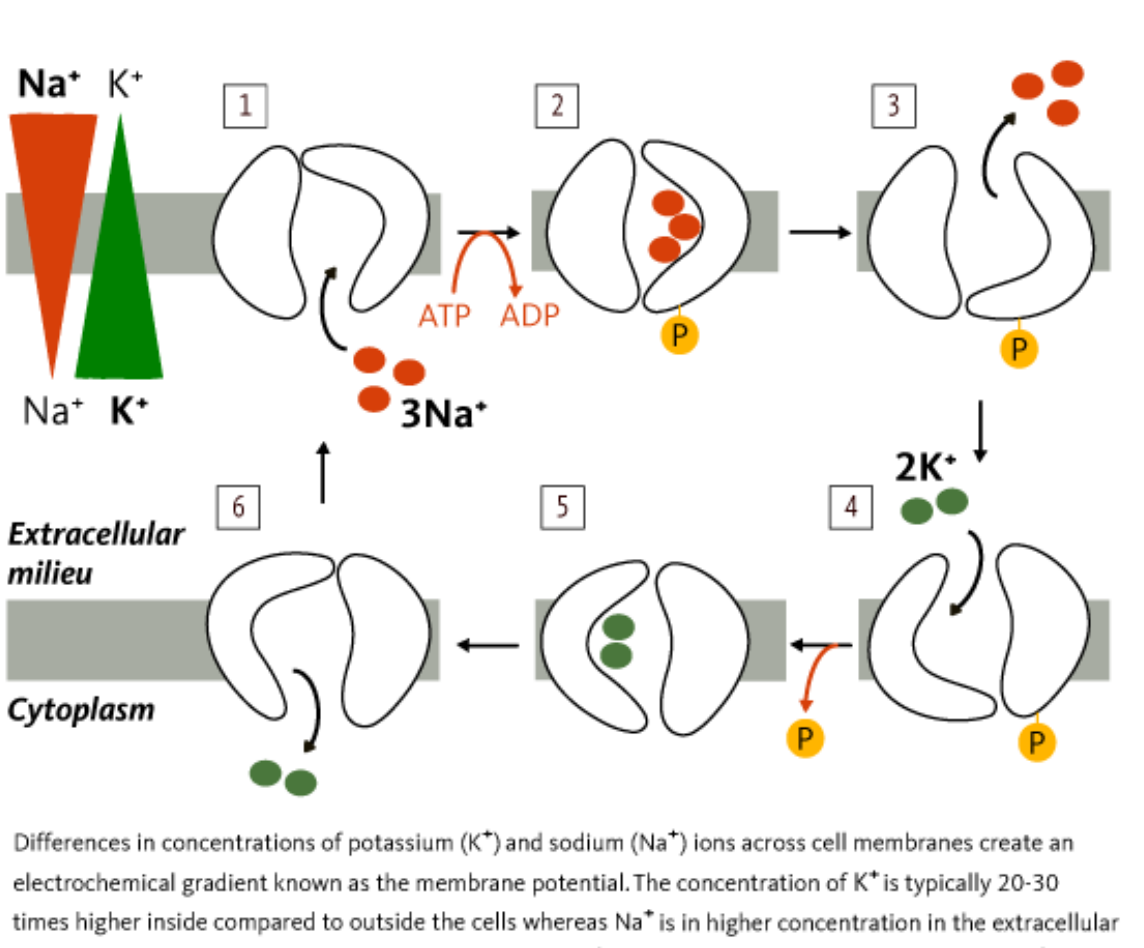
Function

Sodium (Na^+) and chloride (Cl^-) are the principal ions in the extracellular compartment, which includes blood plasma, interstitial fluid (fluid between cells), and transcellular fluid (e.g., cerebrospinal fluid, joint fluid). As such, they play critical roles in a number of life-sustaining processes.

Maintenance of membrane potential

Sodium and chloride are electrolytes that contribute to the maintenance of concentration and charge differences across cell membranes. Potassium (K^+) is the principal positively charged ion (cation) inside of cells, while sodium is the principal cation in extracellular fluid. Potassium concentrations are about 30 times higher inside than outside cells, while sodium concentrations are more than 10 times lower inside than outside cells. The concentration differences between potassium and sodium across cell membranes create an electrochemical gradient known as the membrane potential. A cell's membrane potential is maintained by ion pumps in the cell membrane, especially the Na^+/K^+ ATPase pumps. These pumps use ATP (energy) to pump sodium out of the cell in exchange for potassium (**Figure 1**). Their activity has been estimated to account for 20%-40% of the resting energy expenditure in a typical adult. The large proportion of energy dedicated to maintaining sodium/potassium concentration gradients emphasizes the importance of this function in sustaining life. Tight control of cell membrane potential is critical for nerve impulse transmission, muscle contraction, and cardiac function (2-4).

Figure 1. A Simplified Model of the Na^+/K^+ATPase Pump



Differences in concentrations of potassium (K^+) and sodium (Na^+) ions across cell membranes create an electrochemical gradient known as the membrane potential. The concentration of K^+ is typically 20-30 times higher inside compared to outside the cells whereas Na^+ is in higher concentration in the extracellular compared to the intracellular compartment. Therefore, K^+ diffuses easily out of the cells whereas Na^+ diffuses easily into the cells. The Na^+/K^+ ATPase pump is thus required to maintain the membrane potential by pumping Na^+ out of the cells and K^+ into the cells. In the presence of magnesium (Mg^{2+}), adenosine triphosphate (ATP) provides the energy to translocate 3 Na^+ ions and 2 K^+ ions across the plasma membrane against their concentration gradients. The binding of ATP and magnesium (Mg^{2+}) allows the enzyme to adopt a conformation that opens toward the cytoplasm for the binding and the translocation of Na^+ ions; In turn, the binding of K^+ ions induces the release of phosphate and Mg^{2+} and the translocation of K^+ ions to the cytoplasm.

[Figure 1 - Click to Enlarge]

Nutrient absorption and transport

Absorption of sodium in the small intestine plays an important role in the absorption of chloride, amino acids, glucose, and water. Similar mechanisms are involved in the reabsorption of these nutrients after they have been filtered from the blood by the kidneys. Chloride, in the form of hydrochloric acid (HCl), is also an important component of gastric juice, which aids the digestion and absorption of many nutrients (5).

Maintenance of blood volume and blood pressure

Because sodium is the primary determinant of extracellular fluid volume, including blood volume, a number of physiological mechanisms that regulate blood volume and blood pressure work by adjusting the body's sodium content. In the circulatory system, pressure receptors (baroreceptors) sense changes in blood pressure and send excitatory or inhibitory signals to the nervous system and/or endocrine glands to affect sodium regulation by the kidneys. In general, sodium retention results in water retention, and sodium loss results in water loss (6). Below are descriptions of three mechanisms contributing to a larger multifactorial homeostatic control system that governs blood volume and blood pressure through regulation of sodium balance. These regulatory mechanisms are especially important for the control of sodium transport in various segments of the nephron (basic structural unit of the kidney), including the proximal and distal convoluted tubules, the thick ascending limb of the loop of Henle, and the collecting duct.

Renin-angiotensin-aldosterone system

In response to a significant decrease in blood volume or pressure (e.g., serious blood loss or dehydration), the kidneys release renin into the circulation. Renin is an enzyme that splits a small peptide (angiotensin I) from a larger protein (angiotensinogen) produced by the liver. Angiotensin I is split into a smaller peptide (angiotensin II) by angiotensin converting enzyme (ACE), an enzyme present on the inner surface of blood vessels and in the lungs, liver, and kidneys. Angiotensin II stimulates the constriction of small arteries, resulting in increased blood pressure. Angiotensin II is also a potent stimulator of aldosterone synthesis by the adrenal glands. Aldosterone is a steroid hormone that acts on the kidneys to increase the reabsorption of sodium and the excretion of potassium. Retention of sodium by the kidneys increases the retention of water, resulting in increased blood volume and blood pressure (7).

Anti-diuretic hormone

Secretion of anti-diuretic hormone (ADH; also known as arginine vasopressin [AVP]) by the posterior pituitary gland is stimulated by a significant decrease in blood volume or pressure. In conjunction with the renin-angiotensin-aldosterone system, ADH stimulates epithelial sodium channels (ENaC) in apical cell membranes along kidney nephron distal tubules to increase the reabsorption of sodium and water (8).

Dopaminergic system

Dopamine is produced from L-DOPA in the kidney proximal tubules and acts on dopamine receptors distributed along the proximal tubules and the thick ascending limbs of the loop of Henle to regulate sodium transport. Dopamine promotes sodium excretion (natriuresis) by inhibiting the Na^+/H^+ exchanger and Na^+/phosphate (Pi) co-transporter in apical cell membranes and the Na^+/bicarbonate (HCO_3^-) co-transporter and Na^+/K^+ ATPase in basolateral cell membranes. The inhibitory effect of dopamine on Na^+/K^+ ATPase is enhanced by the natriuretic hormone, atrial natriuretic peptide (ANP), which is secreted by heart muscle cells into the circulation (9).

Deficiency

Hyponatremia, defined as a serum sodium concentration ($[Na^+]$) <136 mmol/liter (mM), may result from increased fluid retention (dilutional hyponatremia) or increased sodium loss. Inadequate sodium intakes rarely result in hyponatremia, even in those on very low-salt diets, because the kidneys increase the excretion of water in order to maintain serum osmolality (i.e., electrolyte-water balance). The results of the 1999-2004 US National Health And Nutrition Examination Survey (NHANES) indicated an overall prevalence of hyponatremia of 1.9% in a US population representative sample of 14,697 participants aged 18 and older (10). Hyponatremia was found to be more prevalent among older individuals (3.1% in those aged 65 to 84 years) and in those suffering from hypertension (2.9%), diabetes mellitus (3.3%), coronary heart disease (CHD; 2.6%), stroke (3.6%), chronic obstructive pulmonary disease (COPD; 3.9%), cancer (3.4%), and psychiatric disorders (2.9%) (10). Hyponatremia is also common in hospitalized patients, with an estimated 15%-30% having mild hyponatremia (serum $[Na^+]$: 130-135 mM) and up to 7% having moderate-to-severe hyponatremia (serum $[Na^+]$ <130 mM) (11).

Causes of hyponatremia

Dilutional hyponatremia may be due to inappropriate anti-diuretic hormone (ADH) secretion, which is associated with disorders affecting the central nervous system, and with use of certain drugs (see Drug interactions). In some cases, excessive water intake may also lead to dilutional hyponatremia (see also Exercise-associated hyponatremia). Conditions that increase the loss of sodium and chloride include severe or prolonged vomiting or diarrhea, excessive and persistent sweating, the use of some diuretics, and some forms of kidney disease. Too severe restriction of dietary sodium intake in renal patients with hypertension and congestive heart failure might also result in harmful body depletion of sodium (1).

Exercise-associated hyponatremia

Exercise-associated hyponatremia (EAH) is dilutional hyponatremia occurring in individuals competing in endurance (up to 6 h in duration) and ultra-endurance (>6 h in duration) exercise events, such as marathons, Ironman triathlons, mountain bike races, hiker treks, and open-water ultra-distance swimming events. Of note, symptomatic EAH has been increasingly reported in shorter events, such as half-marathons and sprint triathlons. The development of hyponatremia during or up to 24 h after intense and/or sustained physical activity has been linked to fluid overload due to excessive water intakes, impaired urinary water excretion due to persistent ADH secretion, and very low or very high ambient temperature (12). Risk factors include pre-exercise hyperhydration, use of non-steroidal anti-inflammatory drugs (NSAIDs), and prolonged exercise (>4 h) (reviewed in 12).

Signs and symptoms of hyponatremia

Symptoms of hyponatremia include headache, nausea, vomiting, muscle cramps, fatigue, disorientation, and fainting. Complications of severe and rapidly developing hyponatremia may include cerebral edema (swelling of the brain), seizures, coma, and brain damage. Acute or severe hyponatremia may be fatal without prompt and appropriate medical treatment (13).

Chronic mild hyponatremia has been associated with deficits in gait and attention, falls, and bone loss and fractures, especially in women and the elderly (14, 15). A recent 11-year prospective cohort study in over 3,000 men free of cardiovascular disease (CVD) also reported significantly higher risks of stroke, coronary heart disease, total CVD events, CVD-related mortality, and all-cause mortality in participants with mild-to-severe hyponatremia (serum $[Na^+]$ <139 mM) compared to those with serum $[Na^+]$ between 139 mM and 144 mM (16). In addition, in a meta-analysis of 81 observational studies in patients with diverse medical conditions (including cardiovascular disease, pulmonary infections, and cirrhosis), the risk of mortality was found to be nearly three times greater in hyponatremic compared to normonatremic subjects (17). Improvement or normalization of serum $[Na^+]$ in hyponatremic subjects was associated with a reduced mortality rate in patients with diverse clinical conditions (18).

Drug interactions

Table 1 lists some medications that may increase the risk of hyponatremia (10, 19).

Table 1. Medications that Increase the Risk of Hyponatremia

Medication Family	Examples
Diuretics	Hydrochlorothiazide, Furosemide (Lasix)
Non-steroidal anti-inflammatory drugs (NSAIDs)	Ibuprofen (Advil, Motrin), Naproxen sodium (Aleve)
Opiate derivatives	Codeine, Morphine
Phenothiazines	Prochlorperazine (Compazine), Promethazine (Phenergan)
Serotonin-reuptake inhibitors (SSRIs)	Fluoxetine (Prozac), Paroxetine (Paxil)
Tricyclic antidepressants	Amitriptyline (Elavil), Imipramine (Tofranil)
Individual Medications Associated with Hyponatremia	
Carbamazepine (Tegretol)	
Chlorpropamide (Diabinese)	
Clofibrate (Atromid-S)	
Cyclophosphamide (Cytoxan)	
Desmopressin (DDAVP; nasal or oral)	
Lamotrigine (Lamictal)	
Oxytocin (Pitocin)	
Vincristine (Oncovin)	

The Adequate Intake (AI) for Sodium

In 2019, the Food and Nutrition Board (FNB) of the National Academy of Medicine revised the Dietary Reference Intakes (DRIs) for sodium (20). The FNB did not find sufficient evidence to determine an Estimated Average Requirement (EAR) and derive a Recommended Dietary Allowance (RDA). Instead, they established an adequate intake (AI) for sodium (**Table 2**; 20). Considerations accounted for by the FNB for establishing an AI for sodium included that the available evidence was insufficient to identify adverse health effects associated with low dietary sodium intakes and that there was substantial evidence suggesting potential long-term health benefits associated with reducing habitual sodium intakes below 2,300 mg/day (see The Chronic Disease Risk Reduction Intake for sodium). The AI could not be derived from the average dietary intakes of apparently healthy people in the US since average intake levels are well above 2,300 mg/day (see Sources).

Table 2. Adequate Intake (AI) for Sodium and Sodium Chloride (Salt)

Life Stage	Age	Males and Females Sodium (mg/day)	Males and Females Salt (mg/day)*
Infants	0-6 months	110	280
Infants	7-12 months	370	930
Children	1-3 years	800	2,000
Children	4-8 years	1,000	2,500
Children	9-13 years	1,200	3,000
Adolescents	14-18 years	1,500	3,800
Adults	19 years and older	1,500	3,800
Pregnancy	14-50 years	1,500	3,800
Breast-feeding	14-50 years	1,500	3,800
*The AI for salt corresponds to the AI for sodium multiplied by 2.5.			

Sources

Most of the sodium and chloride in the diet comes from salt (21). Very little sodium occurs naturally in food. Instead, sodium is added to make certain foods shelf stable, and it is ubiquitously used in the US food supply such that all food groups contribute to sodium intake levels (21). It has been estimated that 75% of the salt intake in the US is derived from salt added during food processing or manufacturing, rather than from salt added at the table or during cooking (22). The lowest salt intakes are associated with diets that emphasize unprocessed foods, especially fruit, vegetables, and legumes. Combined data of the US National Health And Nutrition Examination Surveys (NHANES) 2007-2008 and 2009-2010 indicated average dietary sodium intakes of 3,100 mg/day in children (ages, 3-18 years), 3,800 mg/day in adults (ages, 19-50 years), and 3,300 mg/day in older adults (>50 years) (23). Usual intakes were estimated to be 4,400 mg/day and 3,100 mg/day in adult men and women (ages, 19-50 years), respectively. Overall, sodium intakes among males of all age groups were found to be 20%-45% higher than among females (23). These intakes are well above the sodium Chronic Disease Risk Reduction Intake (CDRR) of 2,300 mg/day (see The Chronic Disease Risk Reduction Intake for sodium).

Table 3 lists the sodium content (in milligrams [mg]) of some foods that are high in salt, and **Table 4** lists some foods that are relatively low in salt. Most sodium is consumed in the form of sodium chloride (salt). The salt content of foods can be calculated by multiplying the sodium content by 2.5.

Example: 2,000 mg (2 g) of sodium x 2.5 = 5,000 mg (5 g) of salt.

For more information on the sodium content of foods, search USDA's FoodData Central.

Table 3. Some Foods that are High in Sodium and Salt Content

Food	Serving	Sodium (mg)	Salt (mg)
Cereal, corn flakes	1 cup	182	445
Cereal, bran flakes	1 cup	216	540
Dill pickle	1 spear	283	707
Bread, whole-wheat	2 slices	291	727
Bread, white	2 slices	344	860
Hot dog (beef)	1	409	1,022
Cheese spread, pasteurized	1 ounce	416	1,040
Fish sandwich with tartar sauce and cheese	1 sandwich	582	1,455
Tomato juice, canned, with salt added	1 cup (8 fl. ounces)	615	1,537
Chicken noodle soup, canned	1 cup	789	1,972
Macaroni and cheese, box	1 cup	869	2,173
Corned beef hash	1 cup	972	2,430
Pretzels, salted	2 ounces (10 pretzels)	1,029	2,572
Ham, minced	3 ounces	1,059	2,647
Potato chips, salted	8 ounces (1 bag)	1,196	2,990
Sunflower seeds, dry roasted, with salt added	1 ounce	1,703	4,257

Table 4. Some Foods that are Relatively Low in Sodium and Salt Content

Food	Serving	Sodium (mg)	Salt (mg)
Olive oil	1 tablespoon	0	0
Orange juice, frozen	1 cup (8 fl. ounces)	0	0
Almonds, unsalted	¼ cup	0.3	0.8
Popcorn, air-popped, unsalted	1 cup	1	3
Pear	1 medium	2	5
Mango	1 fruit	4	10
Tomato	1 medium	6	15
Fruit cocktail, canned	1 cup	9	23
Brown rice	1 cup, cooked	10	25
Potato chips, unsalted	8 ounces (1 bag)	18	45
Tomato juice, canned, without salt added	1 cup (8 fl. ounces)	24	60
Carrot	1 medium	42	105

The daily value (DV) for sodium is less than 2,400 mg. The % DV included on the Nutrition Facts label of packaged foods and beverages is meant to help consumers make informed choices and consider the foods with low (≤5% DV per serving) rather than high (≥20% DV per serving) sodium content (24).

Safety

Toxicity

Excessive intakes of sodium chloride lead to an increase in extracellular fluid volume as water is pulled from cells to maintain normal sodium concentrations outside of cells. However, as long as water needs can be met, normally functioning kidneys can excrete the excess sodium and restore the system to normal (1). Ingestion of large amounts of salt may lead to nausea, vomiting, diarrhea, and abdominal cramps (25). Hypernatremia, defined as serum sodium concentrations ($[Na^+]$) >145 mM, is much less common than hyponatremia and rarely caused by excessive sodium intake (e.g., from the ingestion of large amounts of seawater or intravenous infusion of concentrated saline solution) (26). Hypernatremia generally develops from excess water loss (e.g., burns, respiratory infections, renal loss, osmotic diarrhea, hypothalamic disorders) or reduced water intake, frequently accompanied by an impaired thirst mechanism (6). Symptoms of hypernatremia with evidence of dehydration from excessive water loss may include dizziness or fainting, low blood pressure, and diminished urine production. Severe hypernatremia ($[Na^+]$ >158 mM) may result in altered mental status, lethargy, irritability, stupor, convulsions, and coma. Acute brain shrinkage can lead to intracranial and subarachnoid hemorrhage (26).

The Dietary Reference Intakes (DRIs) for sodium were recently revised by the Food and Nutrition Board of the National Academy of Medicine (20). Using a new expanded DRI model, the National Academy of Medicine did not find sufficient evidence of adverse toxicological effects of excessive sodium intake; therefore, they did not establish a tolerable upper intake level (UL) for sodium (20).

Health risks of excess dietary sodium

Hypertension

Normal blood pressure is defined by a systolic blood pressure below 120 mm Hg and a diastolic blood pressure below 80 mm Hg, often noted <120/80 mm Hg (27). Currently, about one-third of US adults have hypertension (blood pressure levels ≥140/90 mm Hg), and another one-third have elevated blood pressure (prehypertension, corresponding to levels ≥120/80 mm Hg and <140/90 mm Hg) that places them at risk for hypertension (28). Chronic hypertension damages the heart, blood vessels, and kidneys, thereby increasing the risk of heart disease and stroke, as well as hypertensive kidney disease. In a number of clinical studies, salt intake has been significantly correlated with left ventricular hypertrophy, an abnormal thickening of the heart muscle, which is associated with increased mortality from cardiovascular disease (29). Several lines of research, conducted over the last decades, have provided evidence of a relationship between sodium consumption and health outcomes. For instance, observational cohort studies, like the well-designed International Study of Salt and Blood Pressure (INTERSALT), have associated excess sodium intake with a progressive increase of blood pressure with age (30, 31). Further, a number of intervention studies, including the Trial of Nonpharmacologic Interventions in the Elderly (TONE), Trials Of Hypertension Prevention (TOHP), and Dietary Approaches to Stop Hypertension (DASH)-sodium, have demonstrated that dietary sodium reduction could effectively prevent or improve hypertension among population subgroups at elevated risk (see Blood pressure clinical trials).

Salt sensitivity: Blood pressure responses to short-term changes in sodium intake are heterogeneous. Indeed, some individuals have little-to-no change in blood pressure in response to sodium manipulation and are identified as "salt-resistant." In contrast, individuals who experience a greater change in blood pressure following dietary sodium manipulation are labeled "salt sensitive" (32, 33). Most of the protocols used in salt sensitivity studies involve extreme manipulations of sodium intake (sodium loading and sodium depletion) over a short timespan of a few days or up to one week. A typical controlled isocaloric intervention may include a two-phase, randomized, cross-over seven-day dietary sodium manipulation with a high-sodium diet (6.9 to 8.1 g/day) and a very-low-sodium diet (0.5 g/day). Salt resistance is often defined as a change of ≤5 mm Hg in 24-h mean arterial pressure (MAP) between a high-sodium diet and a low-sodium diet. Conversely, salt sensitivity is defined by changes of >5 mm Hg in MAP between high- and low-sodium diets (34).

About 26% of normotensive and 51% of hypertensive individuals are estimated to be salt sensitive (35). Salt sensitivity among normotensive subjects has been found to predict future hypertension (36, 37). Long-term prospective cohort studies also provided substantial evidence suggesting that sensitivity to salt may be an independent risk factor for cardiovascular disease (reviewed in 38). Salt sensitivity involves greater sodium reabsorption in the kidney proximal tubules and higher glomerular filtration rate (GFR) on a high-sodium diet than salt resistance. The rise in blood pressure is thought to compensate high sodium and fluid retention by triggering increased renal excretion. Conversely, salt resistance is associated with adequate excretion of excess sodium such that consumption of large amounts of sodium does not markedly increase blood pressure (1).

Earlier observations suggested that certain subgroups of the population, including African Americans, older individuals (>45 years), and hypertensive patients, tended to have greater average blood pressure responses to changes in sodium intake (38). Nevertheless, a recent meta-analysis of randomized controlled trials found marginal ethnic differences in blood pressure response to sodium reduction (for at least one week) compared to previously reported data (39). Research examining a genetic basis for salt sensitivity may eventually lead to better and reliable classification of individuals for salt sensitivity. Yet, at present, the analyses of common variations (known as polymorphisms) in the sequence of specific genes involved in sodium retention by the kidney failed to show consistent results (reviewed in 40). A recent meta-analysis of nine observational studies failed to show significant associations between specific gene polymorphisms in the renin-angiotensin-aldosterone system and blood pressure response to salt (41). Other polymorphisms in genes like those coding for G-protein coupled receptor kinase type 4 (GRK4), epithelial sodium channels (ENaC) and regulators, or α-adducin may favor sodium retention by the kidney, hence predisposing to blood pressure sensitivity to salt (reviewed in 40). Finally, in addition to genetic predispositions, factors like diet quality (e.g., the DASH diet) and body weight probably influence blood pressure sensitivity to salt (38).

Blood pressure clinical trials: Of particular importance are the results of long-term multicenter trials that are the most relevant to clinical and public health practice, i.e., TONE (42), TOHP (43), and DASH (Dietary Approaches to Stop Hypertension)-sodium. TONE showed that modest reduction in sodium intake by about 1.0 g/day (~2.5 g/day of salt) resulted in a better control of hypertension in older adults who initially were on blood pressure medication (42). TOHP-Phase II (the second of two hypertension prevention trials) showed that a similar level of sodium reduction significantly reduced systolic (but not diastolic) blood pressure by 1.2 mm Hg in overweight participants with prehypertension after three years and limited the onset of hypertension by 18% after four years compared to usual care (no dietary intervention) (43, 44). Adherence to the DASH diet, which emphasizes fruit, vegetables, whole grains, poultry, fish, nuts, and low-fat dairy products, was found to substantially lower systolic/diastolic blood pressures by 11.4/5.5 mm Hg in hypertensive and 3.5/2.1 mm Hg in normotensive people compared to a typical US diet (45). The DASH diet is also markedly higher in potassium and calcium, modestly higher in protein, and lower in total fat, saturated fat, cholesterol, red meat, sweets, and sugar-containing beverages than the typical US diet. The DASH-sodium trial compared the DASH diet to a typical US (control) diet at three levels of sodium intake: low (1.5 g/day, current AI), intermediate (2.3 g/day, recommended as an upper level by US dietary guidelines), and high (3.2 g/day, typical US intake) levels (46). At each level of sodium intake, systolic and diastolic blood pressures were systematically lower in (pre)hypertensive people (blood pressure >120/80 mm Hg) consuming the DASH diet compared to the control diet. Reduction of sodium intake also significantly reduced blood pressure in hypertensive consumers of either the DASH diet or the typical US diet. Yet, in prehypertensive participants, the blood pressure-lowering effect of sodium reduction was only significant in those consuming the typical US diet; sodium reduction failed to reduce blood pressure in all prehypertensive participants assigned to the DASH diet, with the exception of African Americans. Compared to the high-salt control diet, average blood pressure in (pre)hypertensive participants on the low-sodium DASH diet was decreased by 8.9/4.5 mm Hg. Results of the DASH trials support the idea that sodium reduction in the context of a healthful dietary pattern offers an effective approach to the prevention and treatment of hypertension (47).

A majority of randomized clinical trials have examined the effect of dietary sodium reduction on blood pressure in (pre)hypertensive rather than in normotensive (normal blood pressure) people. A recent meta-analysis assessed the results of modest sodium reduction from 22 trials in 990 participants with hypertension (blood pressure ≥140/90 mm Hg) and 12 trials in 2,240 participants without hypertension (blood pressure <140/90 mm Hg). A modest sodium reduction by 1.8 g/day (equivalent to 4.4 g/day of salt; based on 24-hour urinary sodium excretions) for at least four weeks decreased systolic and diastolic blood pressure by an average of 5.4/2.8 mm Hg in subjects with hypertension and 2.4/1.0 mm Hg in those without hypertension (48). Another pooled analysis of eight randomized controlled studies demonstrated a dose-response relationship between sodium reduction (by 1.8 to 3.2 g/day) and blood pressure in subjects with blood pressure over 130/80, but there was no such relationship in subjects whose blood pressure was below 130/80 (49).

The 2015-2020 Dietary Guidelines for Americans concurred with the 2013 American Heart Association (AHA)/American College of Cardiology (ACC) Guideline to recommend that individuals who would benefit from blood pressure lowering, particularly prehypertensive and hypertensive adults, should follow the DASH eating pattern to lower sodium intakes (50). Recommendations include sodium intakes of no more than 2.4 g/day, further sodium intake reduction to 1.5 g/day for an even greater blood pressure-lowering effect, or a reduction is sodium intake of at least 1 g/day if sodium intakes of 1.5 g/day or 2.4 g/day cannot be achieved (50, 51).

More information about the DASH diet is available from the National Heart, Lung, and Blood Institute (NHLBI) of the National Institutes of Health (NIH).

Endothelial dysfunction

Early studies in animals and humans reported that high-salt intake was associated with pathological alterations in the structure and function of large elastic arteries, independent of changes in blood pressure (reviewed in 52). Endothelial dysfunction is considered to be an early step in the development of atherosclerosis. Alterations in the structure and function of the vascular endothelium that lines the inner surface of all blood vessels are associated with the loss of normal nitric oxide (NO)-mediated endothelium-dependent vasodilation. Endothelial dysfunction results in widespread vasoconstriction and coagulation abnormalities. The measurement of brachial artery flow-mediated dilation (FMD) is often used as a functional marker of endothelial function; FMD values are inversely correlated with the risk of future cardiovascular events (53).

The link between sodium intake and cardiovascular disease has traditionally involved hypertension. Yet, recent investigations in salt-resistant normotensive individuals have reported that dietary sodium loading could impair endothelial function independent of changes in blood pressure (54, 55). A study using controlled dietary sodium conditions also demonstrated that a high-sodium diet (6.9 g/day for one week) reduced brachial artery FMD to the same extent in salt-sensitive and salt-resistant normotensive participants (56). On the other hand, a three-week dietary sodium intake of 3 g following a baseline intake of 2.4 g/day of sodium did not lower FMD in 36 untreated (pre)hypertensive adults with baseline FMD values significantly lower than those usually observed in healthy normotensive subjects (57). Circulating markers of endothelial function and low-grade inflammation were unchanged; only urinary sodium excretion and systolic blood pressure increased (57).

In healthy normotensive adults in whom FMD significantly decreased following a meal containing 1.5 g of sodium, potassium supplementation (1.5 g) could limit high sodium-induced FMD reduction in the postprandial state (58, 59). In a 12-week, randomized, cross-over study in 25 overweight/obese and normotensive subjects, a diet containing 2.3 g/day reduced FMD after two days and for six weeks, compared to a diet containing 3.5 g/day (60). In another randomized, cross-over, placebo-controlled trial, dietary sodium restriction (1.2 g/day vs. 3.5 g/day) for five weeks significantly lowered systolic (but not diastolic) blood pressure by 12 mm Hg and increased FMD by 68% in 17 (pre)hypertensive subjects (mean age, 62 years) (61). The improvements in both blood pressure and endothelial function suggest that sodium restriction has a strong potential for reducing CVD risk by preserving the vasculature.

Cardiovascular morbidity and mortality

A high dietary sodium intake is a risk factor for cardiovascular disease. A pooled analysis of 13 prospective cohort studies in 177,025 participants followed for 3 to 17 years found greater risks of cardiovascular disease (+17%) and stroke (+23%) with an average difference of 2 g of sodium (5 g of salt) between higher and lower daily consumption across the studies (62). Higher sodium intakes were also found to be associated with an increased risk of stroke (+24%) — but not with the risk of cardiovascular disease or coronary heart disease — in a more recent meta-analysis of 10 prospective cohort studies and randomized controlled trials (63).

A meta-analysis of randomized controlled studies examined the effect of dietary sodium reduction on cardiovascular events and mortality (64). Dietary interventions aiming at reducing sodium intake failed to demonstrate an effect on all-cause mortality in hypertensive and non-hypertensive individuals. Current evidence also fails to support a decrease in cardiovascular morbidity and mortality in patients with hypertension (64). Likewise, the Centers for Disease Control and Prevention (CDC)-sponsored 2013 report on *Sodium Intake in Populations* by the US Institute of Medicine (IOM; renamed the National Academy of Medicine) indicated that evidence was scarce and of poor quality to assess whether sodium intakes below 2.3 g/day may lower the risk of heart disease, stroke, and all-cause mortality in the general US population (65). In addition, the IOM committee found no evidence of benefits but some evidence of potential harm in reducing sodium intakes to 1.5 g/day-2.3 g/day in individuals with diabetes mellitus, kidney disease, or cardiovascular disease (65). However, in a recent review of the literature, the US Agency for Healthcare Research and Quality (AHRQ) identified low strength evidence to suggest that sodium reduction could decrease the risk of a composite measure of cardiovascular outcomes (seven trials) and the risk of combined cardiovascular morbidity and mortality (eight trials) (66).

Gastric cancer

In the evidence-based report, *Food, Nutrition, Physical Activity, and the Prevention of Cancer* (2007), the World Cancer Research Fund/American Institute for Cancer Research concluded that salt was a probable cause of stomach cancer (67). A recent meta-analysis of seven prospective cohort studies in nearly 270,000 participants showed a 68% greater risk of gastric cancer with the highest versus lowest salt intake level (68). Findings from observational studies, conducted mainly in Asian countries, also suggested an increased risk of gastric cancer with high intakes of salted foods, pickled foods, and processed meat products (68-70). Low intakes of fruit and vegetables, which are protective against gastric cancer, in populations with high intakes of salted foods might also contribute to increasing the risk of gastric cancer (69, 71).

Animal studies suggested that high concentrations of salt may damage the cells lining the stomach, potentially increasing the risk of bacterial infection by *Helicobacter pylori* (72, 73) and cancer-promoting genetic damage (74). The colonization by *H. pylori* is a recognized risk factor for gastric cancer. Case-control studies examining the potential interaction between salt intake and *H. pylori* infection in the risk of gastric cancer have provided mixed results (75-78). Although there is little evidence that salt itself is a carcinogen, high intakes of salted foods may increase the risk of gastric cancer in individuals infected with *H. pylori* or exposed to gastric carcinogens (67). Salty foods, like processed meat, cured meat, and salted fish, contain high levels of nitrosated compounds that may contribute to increasing the risk of gastric cancer (67).

Osteoporosis

Osteoporosis is a multifactorial skeletal disorder in which bone strength is compromised, resulting in an increased risk of fracture. Nutrition is one of many factors contributing to the development and progression of osteoporosis. Dietary sodium is a major determinant of urinary calcium loss (79). High-sodium intake results in increased loss of calcium in the urine, possibly due to competition between sodium and calcium for reabsorption in the kidneys or by an effect of sodium on parathyroid hormone (PTH) secretion (see the article on Calcium). Every 1-g increment in sodium (2.5 g of salt) excreted by the kidneys has been found to draw about 26.3 mg of calcium into the urine (79). A study conducted in adolescent girls reported that a high-salt diet had a greater effect on urinary sodium and calcium excretion in White compared to Black girls, suggesting differences among ethnic groups (80). In adult women, each extra gram of sodium consumed per day is projected to produce an additional rate of bone loss of 1% per year if all of the calcium loss comes from the skeleton.

A number of cross-sectional and intervention studies have suggested that high-sodium intakes are deleterious to bone health, especially in older women (81). In particular, high-sodium intake in conjunction with low-calcium intake may be especially detrimental to bone health (82-84). A two-year longitudinal study in postmenopausal women found increased urinary sodium excretion (an indicator of increased sodium intake) to be associated with decreased bone mineral density (BMD) at the hip (85). Linear regression analysis estimated that BMD could be maintained by reducing sodium intake to a level of 2.3 g/day and by increasing calcium intake to 1.2 g/day. A second longitudinal study in postmenopausal women found that habitual sodium intake of approximately 3 g/day was not detrimental to BMD over three years of follow-up (86). Notably, the average calcium intake in this study population was 1.3 to 1.5 g/day — slightly above the RDA for calcium in women over 50 years. Another study in 40 postmenopausal women found that adherence to a low-sodium diet (2 g/day) for six months was associated with significant reductions in sodium excretion, calcium excretion, and aminoterminal propeptide of type I collagen (a biomarker of bone resorption). Yet, these associations were only observed in women with elevated baseline urinary sodium excretions (87). Finally, in a randomized, placebo-controlled study in 60 postmenopausal women, potassium citrate supplementation prevented an increase in calcium excretion induced by the consumption of a high-sodium diet (≥5 g/day of sodium) for four weeks (88).

Kidney stones

Most kidney stones are composed of calcium oxalate or calcium phosphate. Subjects with an abnormally high level of calcium in the urine (hypercalciuria) are at higher risk of developing kidney stones (a process called nephrolithiasis) (89). A large prospective cohort study that followed more than 90,000 women over a 12-year period found that women with a sodium intake averaging 4.9 g/day (12.6 g/day of salt) had a 30% higher risk of developing symptomatic kidney stones than women whose sodium intake averaged 1.5 g/day (3.8 g/day of salt) (90). Because urinary calcium excretion is increased by high sodium intakes (79), dietary sodium restriction may reduce the risk of stone formation, especially in patients with a history of kidney stones, by limiting calcium excretion (91). A five-year, randomized intervention study that enrolled 120 men with idiopathic hypercalciuria (mean age, 45 years) reported that those assigned to a normal-to-high calcium (1.2 g/day) and low-sodium diet (1.2 g/day) had a 49% reduced risk of kidney stone recurrence compared to those on a low-calcium diet (~0.4 g/day) (92).

The Chronic Disease Risk Reduction Intake

In 2004, the Food and Nutrition Board (FNB) of the National Academy of Medicine (formerly, the Institute of Medicine [IOM]) established a tolerable upper intake level (UL) of 2.3 g/day sodium (5.8 g/day of salt) for adults based on the adverse effects of high sodium intakes on blood pressure, a major risk factor for cardiovascular and kidney diseases (93). The 2015-2020 Dietary Guidelines for Americans report also recognizes that excess sodium consumption poses potential health risks and emphasizes the reduction of sodium intake in the context of a healthful dietary pattern, following the UL set by the IOM panel (50).

In a 2019 update of the Dietary Reference Intakes (DRIs) for sodium, the National Academy of Medicine made use of a new expanded DRI model (20). As a consequence, only evidence of a toxicological risk associated with excessive sodium intakes was considered to establish a UL for sodium (20), whereas previously the UL for sodium was based on evidence of any type of adverse effects (93). In addition, the evidence of the relationship between sodium intake levels, blood pressure, and cardiovascular disease — considered toward establishing a UL in the previous report — has now been reviewed to establish a new DRI category, namely the Chronic Disease Risk Reduction Intake (CDRR) for sodium (20).

Using the expanded DRI model, the National Academy of Medicine did not find sufficient evidence of adverse toxicological effects to establish a UL for sodium (20).

In contrast, substantial evidence from trials showing a lowering of the risks of hypertension and cardiovascular disease with reduction of sodium intakes was used to set a CDRR for sodium in apparently healthy adults at 2,300 mg/day (20). The CDRR for healthy adults means that a lowering of usual sodium intakes to at least 2,300 mg/day from higher levels is expected to reduce the risk of chronic disease.

The CDRR values for other ages/life stages have been extrapolated from the CDRR value set for adults using estimated energy requirements; these CDRR-based recommendations for each age/life stage are presented in **Table 5**.

Table 5. Sodium Chronic Disease Risk Reduction Intake (CDRR)-based Recommendations

Age Group	Recommendation
Infants 0-12 months	Not Determined
Children 1-3 years	Reduce intakes if above 1,200 mg/day*
Children 4-8 years	Reduce intakes if above 1,500 mg/day*
Children 9-13 years	Reduce intakes if above 1,800 mg/day*
Adolescents 14-18 years	Reduce intakes if above 2,300 mg/day*
Adults 19 years and older	Reduce intakes if above 2,300 mg/day
*Extrapolated from the adult CDRR using estimated energy requirements.	

Of note, in its 2013 report on *Sodium Intake in Populations*, the FNB committee considered that recommendations to population subgroups, including those who are most sensitive to the blood pressure effects of sodium, like older people (≥51 years), African Americans, and individuals with hypertension, diabetes mellitus, or chronic kidney disease, should be similar to those for the general US population (65). The IOM committee found no supportive evidence to recommend that these subgroups lower their sodium intake to 1.5 g/day or below (65). In contrast, the 2013 American Heart Association (AHA)/American College of Cardiology (ACC) Guideline on Lifestyle Management to Reduce Cardiovascular Risk advises adults with (pre)hypertension to consume no more than 2.4 g/day of sodium, further reduce sodium intake to 1.5 g/day for an even greater blood pressure-lowering effect, or reduce their daily intake by at least 1 g if sodium intakes of 1.5 g/day or 2.4 g/day cannot be achieved (51).

Finally, the 2010 IOM report on *Strategies to Reduce Sodium Intake in the United States* suggested that the US Food and Drug Administration (FDA) revisit the Generally Recognized As Safe (GRAS) status of salt added to processed food, restaurant food, and food additives, in order to reduce the salt content in the food supply and assist in achieving sodium intakes consistent with US Dietary Guidelines and IOM recommendations (21). These recommendations are currently being reviewed by the FDA (22).

Drug interactions

Taking sodium bicarbonate orally may reduce the efficacy of the antibiotic cefpodoxime and the antidiabetic drug chlorpropamide by limiting drug absorption or increasing drug urinary excretion. Intravenous administration of sodium bicarbonate may also reduce the effects of aspirin and the nasal decongestant pseudoephedrine. Excessive intake of sodium bicarbonate may increase the risk of hypokalemia (abnormally low blood potassium concentration) in patients taking potassium-depleting drugs like diuretics (e.g., hydrochlorothiazide, furosemide, or bumetanide), the anti-gout agent colchicine, and calcium- or magnesium-containing antacids (94).

Linus Pauling Institute Recommendation

There is strong and consistent evidence that diets relatively low in sodium (2.3 g/day or less) and high in potassium are associated with decreased risk of high blood pressure and the related risks of cardiovascular and kidney diseases. Moreover, the DASH trial demonstrated that a diet emphasizing fruit, vegetables, whole grains, nuts, and low-fat dairy products substantially lowered blood pressure, an effect that was enhanced by reducing salt intake to 2.3 g/day of sodium (5.8 g/day of salt). The Linus Pauling Institute recommends a diet that is rich in fruit and vegetables (at least 9 servings/day) and limits processed foods that are high in salt.

Older adults (>50 years)

Since sensitivity to the blood pressure-raising effect of salt increases with age, sodium reduction in the context of a healthful dietary pattern may especially benefit older adults, who are at increased risk of high blood pressure, cardiovascular disease, and kidney disease.

Summary

- Zinc is a nutritionally essential mineral needed for catalytic, structural, and regulatory functions in the body. *(More information)*
- Severe zinc deficiency is rare and caused by an inherited condition called acrodermatitis enteropathica. Acquired zinc deficiency is primarily due to malabsorption syndromes and chronic alcoholism. *(More information)*
- Dietary zinc deficiency is quite common in the developing world, affecting an estimated 2 billion people. Consumption of diets high in phytate and lacking foods from animal origin drive zinc deficiency in these populations. *(More information)*
- The recommended dietary allowance (RDA) for adult men and women is 11 mg/day and 8 mg/day of zinc, respectively. *(More information)*
- Long-term consumption of zinc in excess of the tolerable upper intake level (UL; 40 mg/day for adults) can result in copper deficiency. *(More information)*
- Dietary zinc deficiency has been associated with impaired growth and development in children, pregnancy complications, and immune dysfunction with increased susceptibility to infections. *(More information)*
- Supplementation with doses of zinc in excess of the UL is effective to reduce the duration of common cold symptoms. The use of zinc at daily doses of 50 to 180 mg for one to two weeks has not resulted in serious side effects. *(More information)*
- Current evidence suggests that supplemental zinc may be useful in the management of chronic conditions, such as age-related macular degeneration, diabetes mellitus, Wilson's disease, and HIV/AIDS. *(More information)*
- Zinc bioavailability is relatively high in meat, eggs, and seafood; zinc is less bioavailable from whole grains and legumes due to their high content in phytate that inhibits zinc absorption. *(More information)*

Zinc is an essential trace element for all forms of life. Clinical zinc deficiency in humans was first described in 1961, when the consumption of diets with low zinc bioavailability due to high phytate content (see Food sources) was associated with "adolescent nutritional dwarfism" in the Middle East (1). Since then, zinc insufficiency has been recognized by a number of experts as an important public health issue, especially in low-resource countries (2, 3).

Function

Numerous aspects of cellular metabolism are zinc-dependent. Zinc plays important roles in growth and development, immune function, neurotransmission, vision, reproduction, and intestinal ion transport (4). Using data mining approaches, it has been estimated that over 3,000 proteins in humans have functional zinc-binding sites (5). At the cellular level, the function of zinc can be divided into three categories: (1) catalytic, (2) structural, and (3) regulatory (6).

Catalytic role

Over 50 different enzymes depend on zinc for their ability to catalyze vital chemical reactions (7). Zinc-dependent enzymes can be found in all six classes of enzymes (8), as defined by the International Union of Biochemistry and Molecular Biology (9). During enzymatic reactions, zinc may have either a direct catalytic role or a structural role (i.e., stabilizing the structure of catalytic enzymes; see below).

Structural role

Zinc plays an essential role in the folding of some proteins. A finger-like structure, known as a zinc finger motif, stabilizes the structure several proteins. Examples of zinc finger proteins include the superfamily of nuclear receptors that bind and respond to steroids and other molecules, such as estrogens, thyroid hormones, vitamin D, and vitamin A (10). Zinc finger motifs in the structure of nuclear receptors allow them to bind to DNA and act as transcription factors to regulate gene expression (see Regulatory role). Zinc finger motifs are also involved in interactions of proteins with other proteins, ribonucleotides, and lipids (6). Removal of zinc from zinc-containing proteins results in protein misfolding and loss of function.

Metallothioneins are examples of proteins with a zinc-binding motif. Metallothioneins are small metal-binding cysteine-rich proteins with a high affinity for zinc. They work in concert with zinc transporters, regulating free zinc concentrations in the cytosol (11). Metallothioneins are also involved in the regulation of metal ion homeostasis, cellular defense against oxidative stress, and detoxification of heavy metals (11, 12).

The antioxidant enzyme, copper-zinc superoxide dismutase 1 (SOD 1), is made of two identical dimers, each including an active site with a catalytic copper ion and a structural zinc ion. Demetalation of SOD1 has been implicated in the formation of amyloid aggregates in some forms of inherited amyotrophic lateral sclerosis (ALS) — a motor neuron disease leading to muscle atrophy and paralysis (13).

Regulatory role

Zinc finger proteins have been found to regulate gene expression by acting as transcription factors (see above). Zinc also plays a role in cell signaling via the metal-response element (MRE)-binding transcription factor 1 (MTF1); MTF1 has a zinc finger domain that allows its binding to MRE sequences in the promoter of target genes and the subsequent expression of zinc-responsive genes (6). Zinc may also have a direct regulatory function, modulating the activity of cell-signaling enzymes and transcription factors (6). Extracellular zinc can also stimulate a zinc-sensing receptor that triggers the release of intracellular calcium, a second messenger in signaling pathways (14). Zinc has been found to influence hormone release (see Type 2 diabetes mellitus) (15) and nerve impulse transmission (16).

Nutrient interactions

Copper

Taking large quantities of zinc (50 mg/day or more) over a period of weeks can interfere with copper bioavailability. High intake of zinc induces the intestinal synthesis of a copper-binding protein called metallothionein (see the article on Copper). Metallothionein traps copper within intestinal cells and prevents its systemic absorption (see Wilson's disease). More typical intakes of zinc do not affect copper absorption, and high copper intakes do not affect zinc absorption (17).

Iron

Iron and zinc compete for absorptive pathways (18). Supplemental (38-65 mg/day of elemental iron) but not dietary levels of iron may decrease zinc absorption (18, 19). This interaction is of concern in the management of iron supplementation during pregnancy and lactation and has led some experts to recommend zinc supplementation for pregnant and lactating women taking iron supplements (20, 21). Food fortification with iron has not been shown to negatively affect zinc absorption (22). In a placebo-controlled study, supplementation with zinc (10 mg/day) for three months in children aged eight to nine years significantly decreased serum iron concentrations, yet not to the extent of causing anemia (23). Additional randomized controlled studies have reported a worsening of nutritional iron status with chronic zinc supplementation (24, 25).

Calcium

High levels of dietary calcium impair zinc absorption in animals, but it is uncertain whether this occur in humans (17). One study showed that increasing the calcium intake of postmenopausal women by 890 mg/day in the form of milk or calcium phosphate (total calcium intake, 1,360 mg/day) reduced zinc absorption and zinc balance in postmenopausal women (26). However, another study found that increasing the calcium intake of adolescent girls by 1,000 mg/day in the form of calcium citrate malate (total calcium intake, 1,667 mg/day) did not affect zinc absorption or balance (27). Calcium in combination with phytate might affect zinc absorption, which would be particularly relevant to individuals who very frequently consume tortillas made with lime (i.e., calcium oxide). A study in 10 healthy women (age range, 21-47 years) found that high intake of dietary calcium (~1,800 mg/day) did not impair zinc absorption regardless of the phytate content of the diet (28). For more information on phytate, see Food sources.

Folate

The bioavailability of dietary folate (vitamin B_9) is increased by the action of a zinc-dependent enzyme. Accordingly, some studies found low zinc intake decreased folate absorption. It was also suggested that supplementation with folic acid — the synthetic form of folate — might impair zinc utilization in individuals with marginal zinc status (17, 29). However, one study reported that supplementation with a relatively high dose of folic acid (800 μg/day) for 25 days did not alter zinc absorption or status in a group of students being fed a low-zinc diet (3.5 mg/day) (30).

Vitamin A

Zinc and vitamin A interact in several ways. Zinc is a component of retinol-binding protein, a protein necessary for transporting vitamin A in the blood. Zinc is also required for the enzyme that converts retinol (vitamin A) to retinal. This latter form of vitamin A is necessary for the synthesis of rhodopsin, a protein in the eye that absorbs light and thus is involved in dark adaptation. Zinc deficiency has been associated with a decreased release of vitamin A from the liver, which may contribute to symptoms of night blindness that are seen with zinc deficiency (31, 32).

Deficiency

Inherited zinc deficiency

Much of what is known about severe zinc deficiency was derived from the study of individuals born with acrodermatitis enteropathica, a genetic disorder resulting from the impaired uptake and transport of zinc (33). The symptoms of severe zinc deficiency include the slowing or cessation of growth and development, delayed sexual maturation, characteristic skin rashes, chronic and severe diarrhea, immune system deficiencies, impaired wound healing, diminished appetite, impaired taste sensation, night blindness, swelling and clouding of the cornea, and behavioral disturbances. Before the cause of acrodermatitis enteropathica was known, patients typically died in infancy. Oral zinc therapy results in the complete remission of symptoms, though it must be maintained indefinitely in individuals with the genetic disorder (33, 34).

Acquired zinc deficiency

It is now recognized that milder zinc deficiency contributes to a number of health problems, especially common in children who live in low-resource countries. An estimated 2 billion people worldwide are affected by dietary zinc deficiency (3). The lack of a sensitive and specific indicator of marginal zinc deficiency hinders the scientific study of its health implications (8). However, controlled trials of moderate zinc supplementation have demonstrated that marginal zinc deficiency contributes to impaired physical and neuropsychological development and increased susceptibility to life-threatening infections in young children (34). In fact, zinc deficiency has been estimated to cause more than 450,000 deaths annually in children under five years of age, comprising 4.4% of global childhood deaths (35). For a more detailed discussion of the relationship of zinc deficiency to health problems, see the section on Disease Prevention.

In industrialized countries, dietary zinc deficiency is unlikely to cause severe zinc deficiency in individuals without a genetic disorder, zinc malabsorption or conditions of increased zinc loss, such as severe burns or prolonged diarrhea. Severe zinc deficiency has also been reported in individuals undergoing total parenteral nutrition without zinc, in those who abuse alcohol, and in those who are taking certain medications like penicillamine (see Drug interactions) (36).

Individuals at risk of zinc deficiency (6, 36-38):

- Premature and low-birth-weight infants
- Older breast-fed infants and toddlers with inadequate intake of zinc-rich complementary foods
- Children and adolescents
- Pregnant and lactating (breast-feeding) women, especially adolescents
- Patients receiving total parenteral nutrition (intravenous feedings)
- Malnourished individuals, including those with protein-energy malnutrition and anorexia nervosa
- Individuals with severe or persistent diarrhea
- Individuals with malabsorption syndromes, including celiac disease and short bowel syndrome
- Individuals with inflammatory bowel disease, including Crohn's disease and ulcerative colitis
- Alcoholics and those with alcoholic liver disease who have increased urinary zinc excretion and low liver zinc levels
- Individuals with chronic renal disease
- Individuals with sickle cell anemia
- Individuals who use medications that decrease intestinal zinc absorption, increase zinc excretion, or impair zinc utilization (see Drug interactions)
- Older adults (65 years and older)
- Vegetarians: The requirement for dietary zinc may be as much as 50% greater for vegetarians whose major food staples are grains and legumes, because high levels of phytate in these foods reduce zinc absorption (see Food sources) (29).

Biomarkers of zinc status

Currently, there is not a sensitive and specific biomarker to detect zinc deficiency in humans. Low plasma or serum zinc concentrations are typically used as indicators of zinc status in populations and in intervention studies, but they have a number of limitations, including lack of sensitivity to detect marginal zinc deficiency, diurnal variations, and confounding by inflammation, stress, and hormones (38, 39).

The Recommended Dietary Allowance (RDA)

The recommended dietary allowance (RDA) for zinc is listed by gender and age group in **Table 1**. Infants, children, adolescents, and pregnant and lactating women are at increased risk of zinc deficiency. Since a sensitive indicator of zinc nutritional status is not readily available, the RDA for zinc is based on a number of different indicators of zinc nutritional status and represents the daily intake likely to prevent deficiency in nearly all individuals in a specific age and gender group (29).

Table 1. The Recommended Dietary Allowance (RDA) for Zinc

Life Stage	Age	Males (mg/day)	Females (mg/day)
Infants	0-6 months	2 (AI)	2 (AI)
Infants	7-12 months	3	3
Children	1-3 years	3	3
Children	4-8 years	5	5
Children	9-13 years	8	8
Adolescents	14-18 years	11	9
Adults	19 years and older	11	8
Pregnancy	18 years and younger	-	12
Pregnancy	19 years and older	-	11
Breast-feeding	18 years and younger	-	13
Breast-feeding	19 years and older	-	12

Prevention of Diseases or Conditions Related to Zinc Deficiency

Pregnancy complications and adverse pregnancy outcomes

Estimates based on national food supply indicate that dietary zinc intake is likely inadequate in most low- and middle-income countries, especially those in Sub-Saharan Africa and South Asia (40). Inadequate zinc status during pregnancy interferes with fetal development, and preterm neonates from zinc-deficient mothers suffer from growth retardation and dermatitis and are at risk of infections, necrotizing enterocolitis, chronic lung disease, and retinopathy of prematurity (4). Maternal zinc deficiency has also been associated with a number of pregnancy complications and poor outcomes. A recent case-control study conducted in an Iranian hospital reported higher odds of congenital malformations in newborns of mothers with low serum zinc concentrations during the last month of pregnancy (41). A 2016 review of 64 observational studies found an inverse relationship between maternal zinc status and the severity of preeclampsia, as well as between maternal zinc intake and the risk of low-birth-weight newborns (42). There were no apparent associations between maternal zinc status and the risk of gestational diabetes mellitus and preterm birth. However, the conclusions of this analysis were limited by the fact that most observational studies were conducted in women from populations not at risk for zinc deficiency (42).

To date, available evidence from maternal zinc intervention trials conducted worldwide does not support the recommendation of routine zinc supplementation during pregnancy. A 2015 systematic review and meta-analysis of 21 randomized controlled trials in over 17,000 women and their babies found a 14% reduction in premature deliveries with zinc supplementation during pregnancy, mainly in low-income women (43). This analysis, however, did not find zinc supplementation to benefit other indicators of maternal or infant health, including stillbirth or neonatal death, low birth weight, small-for-gestational age, and pregnancy-induced hypertension. There was also no effect of supplemental zinc on postpartum hemorrhage, maternal infections, congenital malformations, and child development outcomes (43). A recent review of 17 trials (of which 15 were conducted in low- and middle-income countries) found that maternal supplementation with multiple micronutrients (including, among others, zinc, iron, and folic acid) reduced the risk of low-birth-weight newborns and small-for-gestational age infants when compared to supplemental iron with or without folic acid (44). While multiple micronutrient supplementation would likely benefit pregnant women with coexisting micronutrient deficiencies in low- and middle-income countries, there is no evidence to recommend zinc supplementation in isolation in pregnant women from any settings (43, 45).

Impaired growth and development

Growth retardation

Significant delays in linear growth and weight gain, known as growth retardation or failure to thrive, are common features of mild zinc deficiency in children. In the 1970s and 1980s, several randomized, placebo-controlled studies of zinc supplementation in young children with significant growth delays were conducted in Denver, Colorado. Modest zinc supplementation (5.7 mg/day) resulted in increased growth rates compared to placebo (46). Several meta-analyses of growth data from zinc intervention trials have confirmed the widespread occurrence of growth-limiting zinc deficiency in young children, especially in low- and middle-income countries (47-49). A 2018 systematic review and meta-analysis identified 54 trials that examined the impact of zinc supplementation during infancy (on average, 7.6 mg/day for 30.9 weeks) or childhood (on average, 8.5 mg/day for 38.9 weeks) on child anthropometric measurements (50). There was evidence of a positive effect of supplemental zinc on children's height, weight, and weight-for-age Z score (WAZ), but neither on height-for-age Z score (HAZ) or weight-for-height Z score (WHZ). In addition, zinc supplementation did not reduce the risks of underweight (WAZ<-2 standard deviation [SD]), wasting (WHZ<-2 SD), or stunting (HAZ<-2 SD) in children (50). Although the exact mechanisms for the growth-limiting effect of zinc deficiency are not known, research indicates that zinc availability affects cell-signaling systems that coordinate the response to the growth-regulating hormone, insulin-like growth factor-1 (IGF-1) (51).

Delayed mental and psychomotor development in young children
